The sixth case was that of a multipara with six living children who, when about seven months pregnant, entered a hospital because of bleeding and presented a picture of complete separation of the placenta. The cervix was said to be dilated to admit three fingers, an easy version was done, and the patient's pulse at the end of operation was 86. Two hours post partum, however, she suddenly became cyanotic and died. It is most likely that embolism was the cause of this death because of its extremely sudden nature, but it is also possible that the version resulted in rupture of the uterus.

The seventh case was that of a multipara who suddenly became pulseless and cyanotic during labor. She was delivered by high forceps but died half an hour after delivery, and pulmonary embolism seems the most likely cause of death.

The eighth patient was an obese woman with large varicosities of the vulva and thighs who was delivered by low forceps; she died six hours after delivery, following an attack of cyanosis and respiratory distress, before a physician could get to her.

The ninth patient ran a slight temperature following a low-forceps delivery; on the eighth postpartum day a sharp pain developed in the left thigh and was followed almost immediately by cyanosis and death. This embolus was septic in origin.

The tenth case was that of a patient who had been delivered by simple low forceps nine days previous to a cholecystectomy, which was performed for an acute cholecystitis. She had an uneventful convalescence until the seventh post-operative day, when she collapsed, became cyanotic and died within fifteen minutes. Pregnancy in this case was merely incidental; death was due to pulmonary embolism following cholecystectomy

(To be concluded)

DEATHS

GEORGE—**LESLIE H. GEORGE, M.D.**, of Haverhill died October 25. He was in his sixty-fourth year.

Born in Dorchester, he attended Clark University and the College of Physicians and Surgeons, Columbia University, and received his degree from Maryland Medical College in 1905.

Dr. George was a former member of the Massachusetts Medical Society and of the staff of Gale Hospital, Haverhill.

TUTTLE—**GEORGE H. TUTTLE, M.D.**, of South Acton, died April 2. He was in his seventy-seventh year.

Dr. Tuttle received his degree from the Harvard Medical School in 1891. He was a member of the Massachusetts Medical Society and the American Medical Association.

WAR ACTIVITIES

OFFICE OF PRICE ADMINISTRATION

GASOLINE AND TIRE RATIONING

The following open letter to all physicians of the United States was recently released by the chief of the Gasoline Rationing Branch, Office of Price Administration:

In the East Coast gasoline-rationing program, made necessary by the shortage of transportation facilities for petroleum products, the indispensability of your profession was recognized by its inclusion in the categories of persons eligible for preferred mileage, that is, necessary occupational mileage in excess of 470 miles a month. Now the Office of Price Administration has been ordered by Mr. William Jeffers to institute and administer a nationwide mileage rationing program for the express purpose of conserving our rubber-borne transportation. In framing the regulations for the new program, your profession was one of the first to be provided for.

If we are to carry out our double task of preventing a collapse of our military and civilian transportation, we must have the complete co-operation of those groups of persons whose driving is deemed essential to the war effort. Our immediate aim is to attain the 5000-mile national mileage average set by the War Relocation Authority as the maximum possible in light of the dire rubber shortage. Our experience with the East Coast program tells us that the preferred categories use one-half the gasoline consumed, though they constitute less than one-fourth the total number of automobile operators. Clearly, then, the great savings of rubber on a nationwide scale must be made in the preferred categories.

Under the regulations governing the mileage-rationing program, physicians are eligible for preferred mileage if their essential occupational needs exceed 470 miles a month and if the mileage is needed for regularly rendering necessary professional services. Mileage traveled daily or periodically between home or lodging and a fixed place of work is not considered preferred. Physicians who conduct their practices in offices, as many specialists do, are not eligible for preferred mileage.

Without question or hesitation, doctors have been and will be granted all the gasoline needed to carry out their professional work. We hope that they will regard their concrete symbol of their indispensability, the C book, as a moral obligation and not as a personal privilege. From another point of view, the C book is part of a doctor's equipment; it should not be used for anything but the work of humanity.

When nationwide gasoline rationing begins, there are certain concrete things a doctor can do to live up to the high ethical standards set for him by his own profession:

(1) At the time of first issuance of rations, he can so carefully compute his necessary mileage as to make a B book adequate for his purposes though he might easily make out a case for a C book which might be granted to him without question by his local war price and rationing board, eager to provide for physicians.

(2) In the computation of his mileage, he can religiously adhere to the provision of the regulations, which makes 150 miles of his basic ration available for occupational purposes. Moreover, he can help mightily in establishing the principles that only 90 miles of the basic ration are to be used for home necessary use and that there is no provision whatever in any ration for pleasure driving.

(3) Conversely, if he should be granted a C book, he can return to the local board, at the end of the three-month period, all unused coupons accruing to him as a result of a quite natural overestimation of needs or of overgenerous 'tailoring' by his board instead of using such coupons for nonessential purposes. The moral effect of such an act on his fellow citizens will be incalculable.

(4) He can set an example by scrupulously observing the 35-mile speed limit, except in cases of emergency, in spite of the fact that doctors could easily get away with it.

(5) Should he be assigned to a hospital, clinic or institution after a ration card for calling on his private practice has been issued, he can use public means of transportation at the price of personal inconvenience.

(6) He can refrain from any kind of driving whatever that might appear to be nonessential in the eyes of the public.

Doctors are the leaders and molders of public opinion in their communities. If the average man has any reason to believe that the professional men whom he regards with great respect are indifferent or hostile to the mileage-rationing program, it will be difficult, if not impossible, to make it effective. Conversely, if doctors as a group observe the letter and spirit of the regulations, they will be a powerful force in making this absolutely mandatory war measure serve its purpose.

pose. We know that we can rely on the support of your profession, which has demonstrated its patriotism, ability and unselfishness at every opportunity.

MISCELLANY

RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR SEPTEMBER, 1942

DISEASES	SEPTEMBER 1942	SEPTEMBER 1941	FIVE-YEAR AVERAGE*
Anterior poliomyelitis	9	66	49
Chicken pox	105	106	89
Diphtheria	11	10	9
Dog bite	870	1153	954
Dysentery, bacillary	6	110	44
German measles	69	28	21
Gonorrhea	521	403	450
Measles	150	168	127
Meningitis, meningococcal	7	8	4
Meningitis, other forms	3	2	†
Mumps	248	233	133
Paratyphoid infections	33	2	10
Pneumonia, lobar	193	106	110
Scarlet fever	316	243	155
Syphilis	460	361	408
Tuberculosis, pulmonary	276	229	243
Tuberculosis, other forms	18	23	24
Typhoid fever	4	7	10
Undulant fever	4	8	4
Whooping cough	778	546	466

*Based on figures for preceding five years.

†Pfeiffer bacillus meningitis only other form reportable previous to 1941.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Amherst, 1; Boston, 2; Fitchburg, 1; Holyoke, 1; Somerville, 1; Stoneham, 1; Weymouth, 1; Williamstown, 1; total, 9.

Diphtheria was reported from: Arlington, 1; Boston, 1; Bourne, 1; Fall River, 6; Lowell, 1; Wrentham, 1; total, 11.

Dysentery, bacillary, was reported from: Boston, 2; Lynn, 1; Salem, 3; total, 6.

Encephalitis, infectious, was reported from: Lowell, 1; Northampton, 1; total, 2.

Malaria was reported from: Arlington, 1; Boston, 1; Camp Edwards, 4; total, 6.

Meningitis, meningococcal, was reported from: Boston, 1; Cambridge, 1; Melrose, 1; New Bedford, 1; West Springfield, 1; Weymouth, 1; Worcester, 1; total, 7.

Meningitis, other forms, was reported from: Avon, 1; Plymouth, 1; Randolph, 1; total, 3.

Paratyphoid infections were reported from: Andover, 1; Boston, 11; Brockton, 1; Cambridge, 3; Framingham, 1; Greenfield, 2; Hull, 1; Mansfield, 1; Quincy, 4; Salem, 1; Somerville, 2; Walpole, 1; Waltham, 4; total, 33.

Septic sore throat was reported from: Boston, 1; Cambridge, 1; Fort Banks, 1; Ipswich, 2; Williamstown, 1; total, 6.

Tetanus was reported from: Plymouth, 1; Springfield, 1; total, 2.

Trachoma was reported from: Boston, 1; total, 1.

Typhoid fever was reported from: Arlington, 1; Everett, 1; Gloucester, 1; Pittsfield, 1; total, 4.

Undulant fever was reported from: Blandford, 1; Chat-ham, 1; Mattapoisett, 1; Somerville, 1; total, 4.

Weil's disease was reported from: Boston, 1; total, 1.

Communicable diseases reported at figures above their respective five-year averages were chicken pox, diphtheria, measles, meningococcal meningitis and lobar pneumonia.

Record-high figures were attained for German measles, paratyphoid infections, whooping cough and mumps. The latter, after a month's drop from record figures, is back again in the record column for the thirteenth time during the past fifteen months.

Diseases reported at figures below their five-year incidences were anterior poliomyelitis, dog bite and bacillary dysentery.

Typhoid fever and tuberculosis, other forms, were reported at record-low incidences.

Undulant fever was reported at a figure equal to its five-year average.

Two cases of animal rabies were reported from the focus in the northeastern section of the State.

CORRESPONDENCE

ROTATING INTERNSHIPS

To the Editor: To prepare physicians for war service, the members of the Medical Staff of the Salem Hospital are convinced that the rotating internship, with a knowledge of the Army and Navy requirements for young doctors, is a responsibility of hospitals today. It is not fair to a young doctor to place him in the Army or Navy without certain basic training that will enable him to meet emergency conditions that he might be called on to meet unaided.

The Salem Hospital has offered rotating internships for many years and has been accredited for the training of interns by the American Medical Association since accreditation was first offered. Both the administrative office of the hospital and its medical staff have taken this job very seriously.

Although we have endeavored to give each intern instruction and practice in all departments, eighteen months, or even two years, is too short for any of them to become expert in any one department. We have therefore tried to impress on them that if they wish to become specialists in any branch of medicine, they should seek a further internship or residency devoted exclusively to the specialty of their choice. This, many of them have done.

Now the war has changed all that, and the young doctor must get the most he can out of a one-year internship and we must see to it that he does. Whether it is worth while to help an intern through an occasional appendectomy or hernia or give him instruction in spinal anesthesia during that short service has been, and still is, a much-disputed problem. Some men react quickly and seem to profit; with others, one feels that the time spent is wasted. However, we have given them the benefit of the doubt and offered that instruction.

An incident that recently came to our notice encourages us to believe that at least during the emergency this is the right thing to do, and seems worth reporting. One of our interns who graduated last June immediately enlisted in the Navy. In due course of time, he was assigned as medical officer to a vessel and sent to sea in company with other naval ships. During the voyage, a seaman in an accompanying ship developed acute appendicitis. The medical officer of that ship had had a straight medical internship and knew little or nothing about operating. The commanding officer therefore transferred our ex-intern to that ship in mid-ocean, where he was able to give the seaman spinal anesthesia and to remove successfully the af-

ing appendix The sailor had a speedy and uneventful
nvalence
his episode is offered with all due modesty as an in
mauve rather than a laudatory message.

MEDICAL EDUCATION OF THE PUBLIC

To the Editor Permit me to commend you for the
and you take in relation to such articles as the one
ublished in *Reader's Digest* regarding the 'one-day cure
r syphilis' There may be grave consequences from
ublication of such unfinished investigations, certainly not
uch good will be accomplished Contradiction or even
discussion serves only to attract the attention of the mor-
idly curious or innocently interested portion of the
public However, I do not expect that your editorial nor
ny feeble protest will have any effect on a magazine
which is inclined to print that brand of literature

Married Love and Should My Boy Be Circum-
cised might be quite appropriate in a medical journal
ut to my way of thinking are decidedly out of place in a
widely read and indiscriminately circulated magazine
uch as the one that published them, especially one that
aters to and seeks actively a circulation among school
children

I know, because I have tried, how little effect criticism
has upon such publishers As a defense, for instance, I
was informed that one of the articles was timed so as to
appear in a summer time issue when the schools were not
in session So I have become a trifle more circumspect
in selecting reading matter for my office as well as for my
home

JOHN V. GALLAGHER, M.D.

Milford, Massachusetts

REPORT OF MEETING

BOSTON CITY HOSPITAL HOUSE OFFICERS ASSOCIATION

At the first of a series of meetings on war medicine,
sponsored by the Boston City Hospital House Officers
Association, Dr. Harold W. Brown, dean of the School
of Public Health at the University of North Carolina,
spoke on 'Parasitic Disease Prevalent in the African and
Pacific Theaters of War'

The chief problem in the management of tropical dis-
eases is the institution of therapy at an early date to pre-
vent the otherwise chronic and disastrous sequelae of most
of these infections The aim, then, should be to sharpen
ones diagnostic acumen in these diseases, which hereto-
fore have merely been a textbook picture to most physi-
cians To prevent or decrease the number of cases, one
must be acquainted with the source of the infection, the
vectors involved in its transmission, and the habits of man
that make infestation possible The problem is not con-
fined to the actual theaters of war, for these diseases on
the whole are not self limited and may be brought home
by returning troops, where they may cause disease in the
civilian population Some parasites may even become in-

digenous in this country if the proper vector is present and
the habits of man are favorable for its perpetuation But
many of the fears so far expressed are probably unfounded,
for most of the parasitic diseases brought back will dis-
appear through death of the parasite, host or vector

One of the common conditions encountered in the
tropics is filariasis, most commonly caused by *Filaria ban-
crofti* This is found in this country only in Charleston,
North Carolina, but is very prevalent in North Africa,
India, the Pacific islands and Australia As an example,
15 per cent of the inhabitants of the Solomon Islands
have elephantiasis and many more must harbor the para-
site Transmission is accomplished by the female of all
genera of mosquitoes, in distinction to malaria The
microfilaria enter the blood stream and muscle of the
insect from the alimentary tract and thence migrate to
the proboscis in the course of a few weeks, where they
are ready for reinjection into the host They are found
in the blood stream in greatest numbers and sometimes
only during the night, so smears should be taken at that
time They require about a year to mature in the blood
stream of the host They then find their way to the
lymph channels where they reproduce Although many
people infected with the parasite show no symptoms, re-
current lymphangitis and elephantiasis are frequent late
manifestations Recurrent lymphangitis may be caused
by the death of the parasites and the absorption of some
toxic substance Elephantiasis may be initiated and cer-
tainly can be continued in the absence of any filaria There
seems to be an original lymph stasis, which is perpetuated
in some unknown manner Streptococcal infection may
play a major or minor role, according to various ob-
servers Although 95 per cent of elephantiasis occurs in
the lower extremity, the scrotum, vulva and breasts are not
uncommon sites for the condition Treatment of this
group of diseases has so far been unsatisfactory, arsenical
and antimony compounds being the drugs most widely
employed There is some question concerning the ef-
ficacy of killing the parasites, since this may initiate either
of the late manifestations mentioned above Although
this condition has been present in Charleston for a cen-
tury, there has been no spread, so we may be fairly con-
fident that it will not assume any great proportions in
this country

The second large group of parasites are the schistosomes
which live in the blood vessels of man and produce symp-
toms referable to the site of predilection of each species
Schistosomum hematobium, which invades the vessels of
the urinary bladder, is distributed widely in North
Africa, and over 50 per cent of the population of Egypt
is infected *S. mansoni* is also found in that region as well
as in South America and some of the Pacific islands Its
site of predilection is the liver and portal system, where it
causes ascites, various abdominal complaints and great
emaciation *S. japonicum* is most prevalent in Japan but
is also found in certain sections of the China coast Trans-
mission is from man to water snail to man The eggs must
fall in water, where the miracidial form is taken up by
the snail Here the development takes place whereby the
cercarial form is attained, and thus then enters the human
host Spines aid in the penetrating tactics of the parasites,
but there is some question whether a latic fluid is se-
creted The adult form lives in man, and the fact that
the eggs must fall in water may prevent the transmission
of the disease in this country The same genus is found
here, but for some reason these snails do not seem to be
satisfactory as a vector The conditions favoring the spread

in Asiatic and African countries, which do not obtain here, are the use of human feces for fertilizer (Asia) and defecating in or near water (Egypt).

The trypanosomes comprise one of the largest groups of pathogenic parasites. They are widely distributed in the areas where troops are now engaged in combat, and cause sleeping sickness and Chagas's disease. *Trypanosoma gambiense*, *T. rhodesiense* and so forth, which were formerly considered different, are probably the same species with various reactions dependent on the immunologic background of the host. The tsetse fly is the only known vector, and it is not found in this country; but the black (biting) stable fly of this country can mechanically transmit the parasite. Therefore the disease is possible but not very probable here. Chagas's disease, in South America, is transmitted by the *Glossina palpalis*. The cycle in the fly requires several days. Reservoirs or natural sources of these diseases are found in some antelope. Formerly as many as 50 per cent of the population of a community died each year with trypanosomiasis. The early manifestations include a rash, enlargement of the posterior cervical lymph nodes and orbital edema. At autopsy the brain usually reveals a typical nonspecific perivascular cuffing. There are two forms of treatment. The first is Bayer 205 (Germanin), which is administered intravenously. The initial dose is 0.3 gm., to test the sensitivity of the patient; if no untoward effects result, this is followed by the therapeutic dose—1.0 gm. in 10 cc. of fluid, to a total of 10 gm. There are a considerable number of reactions, some of which are fatal. Tryparsamide and other arsenicals are also employed. The former is given in a dose of 0.045 gm. per kilogram of body weight for eight to fifteen weekly injections. The main complication following the use of this drug is optic atrophy.

Other parasites commonly encountered in the tropics are the *Leishmania*. *Leishmania donovani*, found in North Africa, Asia, India and China, causes the visceral form of kala-azar. *L. tropica*, found in about the same sectors, causes a cutaneous form of the disease called Oriental sore. *L. braziliensis* also causes a cutaneous form and is prevalent in South America and even Central America. The vector is presumed to be phlebotomus, which is able to pass through most mosquito netting. It is also found in bedbugs but apparently cannot be transmitted by them. In this country the responsible mosquito is found only on Plummer's Island, off the coast of Maryland. The parasite is found in the leukocytes in man. The clinical manifestations of the visceral type are an enlarged abdomen from hepatomegaly and splenomegaly; of the cutaneous type, a chronic moist ulcer; and of the South American form, mucous-membrane lesions as well as cutaneous sores. Treatment of leishmaniasis was formerly carried out with potassium and sodium antimony tartrate, but these have now been supplanted by the pentavalent antimony compounds, such as Neostibosan. The cutaneous forms are treated by these drugs, but also receive irradiation and carbon dioxide snow.

In summary, Dr. Brown emphasized that although the habits and the lack of suitable vectors militate against endemic foci of these tropical diseases in this country, occasional cases will be brought back that have been misdiagnosed or inadequately treated. It was pointed out in passing that, although malaria is now endemic in this country in mild form, more severe forms may be brought back to plague a nonresistant host.

BOOK REVIEWS

Roentgen Treatment of Infections. By James F. K. M.D. With the collaboration of D. Arnold Dowell, M.D. 8°, cloth, 432 pp., with 122 illustrations and 25 tables. Chicago: The Year Book Publishers, Inc., 1942. \$6.00.

The title of this book suggests that it is a discussion of the roentgen treatment of all the various types of infectious process in which such treatment has been found of value. Actually its main thesis concerns the roentgen treatment of gas gangrene. To the reviewer it seems that all the pertinent facts concerning the treatment of this condition might have been clearly set forth in a treatise of some 25 pages, but instead the authors ramble through slightly more than 400 pages.

The first two chapters, amounting to about 100 pages, comprise a very elementary discussion of the early history of roentgenology, the physics of roentgenology and roentgen dosage. This discussion adds little to the value of the book.

The authors point out that the mortality from gas gangrene at the close of the last century was 50 per cent and that this rate continued through World War I: up to 1928, when roentgen treatment was first used. In their most recent series of 42 cases the rate was reduced to 5 per cent. They are opposed to the use of serum and also to the use of sulfanilamide and related compounds. They believe that débridement should be carried out only after several days of roentgen therapy, since much of the tissue that is at first discolored will later regain full vitality. The dosage recommended is about 70 r twice daily for two or three days and then once daily for several more days. The total dose rarely exceeds a threshold erythema.

There are somewhat shorter discussions of the treatment of such conditions as peritonitis, carbuncles, parotitis, mastoiditis and pneumonia.

The History and Evolution of Surgical Instruments. By Dr. C. J. S. Thompson. With a foreword by Dr. Chas. D. Leake, M.D. 4°, cloth, 113 pp., with 115 illustrations. New York: Schuman's, 1942. \$8.50.

This book is an excellent general historical survey of the surgeon's tools from the paleolithic period to the beginning of the present century. The author bases his discussion on the famous collection of surgical instruments in the possession of the Royal College of Surgeons, of which he was curator. Excellent reproductions and descriptions are given of scalpels, amputation knives, saws, trepans, vaginal dilators and speculums, head saws, artery and dressing forceps, bullet-forceps and extractors, instruments for phlebotomy and venesection, tourniquets, tractors and operating tables. The author makes special note of the famous surgeons who used these instruments.

The value of this book is measurably increased when one reads the following words: "We have suffered a grievous calamity in the almost total loss of our incomparable collection of surgical instruments at the Royal College of Surgeons. High explosives reduced the interior of the museum to ruins and the historical instruments of the museum were burnt out. It is a terrible loss as only a few specimens were saved." This book is worthy of being owned by all surgeons and should of course be in every library.

NUMBER 22

THE SEQUELAE OF WAR HEAD INJURIES (Concluded)*

D. DENNY-BROWN, M.B., D.Phil., F.R.C.P.†

BOSTON

ESTIMATION OF DEGREE OF GENERAL INJURY

Much depends on how severity of injury is defined. It soon became apparent to me that a "severe" injury is not necessarily associated with an extensive wound, laceration, depressed fracture or other surgical complication. I refer to the type of case in which unconsciousness is prolonged for a day or several days, and succeeded by confusion or delirium for many more days. Such a state is commonly called "cerebral contusion"^{32, 35} or "cerebral edema"³⁶—according to the particular theory to which the diagnostician adheres, and supported by evidence of subarachnoid hemorrhage or focal signs on the one hand, or increased cerebrospinal-fluid pressure on the other. But, with increasing experience, one soon finds that cases, such as Case 5 cited above, occur without either of these signs, or hemorrhage or increase of pressure. Furthermore, accessory methods, such as the air encephalogram, which gives very definite evidence of any local lesion, may fail to give any such indication. The injury should nevertheless be called severe. Conversely, many patients suffer epidural or subdural hemorrhage and make a rapid and permanent recovery immediately after its surgical relief. From the point of view of the persistent effect on the brain, such complications of injury must therefore be termed slight. When persistent symptoms follow relief of such a complication, the cause must be sought in some further condition—psychoneurotic, general intellectual impairment or some other.

The difficulty most writers have in accepting the entity "concussion" is that it is defined only in negative terms. If one accepts absence of contusion, edema and hematoma as its characteristics, how is one to know that a minimal degree of any or all of these entities is not present, or not de-

tectable by the relatively coarse methods of examination? The answer is twofold: concussion has been shown experimentally to occur as an *immediate* paralysis without such changes (Denny-Brown and Russell²² and Williams and Denny-Brown²³); and the electroencephalogram gives a clear indication of the presence of this condition. In traumatic coma and confusion, great slowly rolling electrical fluctuations at a rate of 1 per second occur uniformly over the entire cerebral cortex. Greatly increased intracranial pressure sometimes causes a similar state, and this possibility should be eliminated. As coma passes into confusion and delirium, faster rhythms appear. Long after the confusion has passed and normal rhythm has been established, slow undulation of the base line reflects the ground swell of the previous storm. This electrical disorder observed in my cases has been analyzed in detail and reported independently by Williams,^{11, 34} who was electroencephalographer to the hospital. The important clinical features are that the disorder is generalized (the electroencephalogram of focal contusion is focal), that it can occur without increased pressure or blood in the cerebrospinal fluid, and that it can subside at variable speeds, in from less than an hour to six months.

It is submitted, therefore, that a severe generalized disorder—for which there is at present no better name than concussion, traumatic confusion or stupor³⁷—may occur without the surgical complications that are generally described. If the progression of such coma were followed through a period of confusion lasting days, or even only one day, to recovery, one would undoubtedly rate the disturbance as severe. More difficulty arises in the interpretation of the electroencephalogram if the patient is seen for the first time months after the injury, especially when, as is common in war, accurate details of the illness are no longer available. The patient has no memory of his condition. The skull or x-ray film, or at this late date the electro-

*Presented in abbreviated form at the annual meeting of the Massachusetts Medical Society, Boston, May 27, 1942.

†Professor of neurology, Harvard Medical School; director of the Neurological Unit, Boston City Hospital; and Captain, Royal Army Medical Corps Reserve.

encephalogram, may show no objective mark of the injury or only such slight disorder as to be within the possible limits of normal variation. How, then, should the illness be judged?

The most reliable criteria found have been the duration of the post-traumatic amnesia (Russell^{16, 19}) and the defects in the intellectual status. Supporting evidence may or may not be had from the air encephalogram (dilatation of the ventricles) and electroencephalogram, depending on the time since injury.

Recently some remarks have been made deprecating acceptance of the patient's statement of his own amnesia as evidence of injury,³⁰ so far as industrial and civil accidents are concerned. Although such an objective approach to this problem is desirable, a critical questioning of the patient (particularly when he is a member of the armed forces) by a trained observer soon reveals whether his story of amnesia rings true or not, and experience in assessing large numbers of such cases has confirmed this view.

The investigation of an amnesia is too large a subject to be dealt with fully here, but the following general statements may be helpful. True concussion should be followed by retrograde amnesia, which should gradually shrink to a fixed absolute minimum. Thus, the concussed patient should not recollect the injury. The post-traumatic amnesia should not have a sharp end point, and persistent errors in judgment and difficulty in concentration should long outlast it. What the patient was told of his behavior while in the hospital should be consistent with the type of recovery known to follow a state of true confusion—for example, his inability to recognize relations or friends in spite of recovery for simple conversation. That hallucinations or manic behavior color this stage is an indication of the personality of the patient rather than of the actual nature of the injury. Thus, the trained and experienced observer will know whether amnesia is true or false. False amnesias include those of simulation and those of hysterical states. In doubtful cases, these can be recovered by treatment with Amytal or other hypnosis, whereas true traumatic amnesia cannot. If surgical complications occurred, it is essential to know whether amnesia terminated with their relief. If not, a state of general confusion may be assumed to have coexisted and undergone independent later recovery. Subject to these limitations, then, the duration of blank in memory in the mind of the patient from the time of injury onward is a very good index of the severity of generalized or concussive effect. It indicates the total duration of coma and subsequent confusion, and thus the general severity of the injury may be estimated. The

onset of the amnesic period should have been immediate. When the amnesic state had an onset at an interval after the injury, a surgical complication—such as subdural or extradural hematoma—or a hysterical episode must be suspected.

After evidence of a severe or moderately severe injury has been sought, inquiry is directed to signs of persistent damage to cerebral function. The most crucial and difficult to define is intellectual deficit. There may be a history of defects in judgment or slowness in cerebration, or of apathy since the injury. It is only to be expected that such a widespread intellectual disorder as disorientation and confusion lasting for several days or weeks should leave its mark on later intellectual function, and the clinical application of any good tests of intellectual status will define the defect. Some estimate of the intellectual level of the patient before the injury, on a basis of education and employment, must be made. In coarser degrees of deficit, tests for memory, such as digit retention, the serial subtraction of 7, test stories and general information, show marked deficiencies. In the slighter degrees of disorder, tests of judgment, the use of intelligence scales, such as the Matrix test, general tests, such as the Rorschach test, detection of absurdities and so forth, may be required to define the persistent defect.

To clarify my approach to the problem, a type of case is cited in which the injury induced a generalized cerebral disorder of relative purity (traumatic delirium or traumatic stupor). I believe that such disorder exists in some degree in all severe and many moderately severe head injuries, complicated by various combinations of contusion and edema, laceration, hematoma, subarachnoid hemorrhage, and fracture. However dangerous or alarming these complications may be immediately after the head injury, experience has shown that no one is alone responsible for long-continued disability. *The essential factor that retards or prevents full restitution of cerebral capacity is the generalized cerebral disorder*, of which the best indices are the duration of true post-traumatic amnesia and a residual intellectual deficit.

In the last thirty years, a continuous search for objective evidence of the post-traumatic cerebral syndrome has been made.¹⁸ Such criteria as increased reflexes, loss of visual convergence, change of pulse rate with posture³⁸ or with adrenalin, rise of cerebrospinal-fluid protein, slowness of cerebrospinal-fluid resorption,³⁹ persistent rise of cerebrospinal-fluid pressure^{39, 40} and, paradoxically, persistent lowering of cerebrospinal-fluid pressure⁴¹ have all had their advocates, but none have stood the test of experience. The first three listed, for example, are common in psychoneurotic states; a

high cerebrospinal-fluid protein is very seldom seen and, when present, indicates organic damage. A long-maintained, definite abnormality in cerebro-

FIGURE 7. Lance Corporal S.

This is a half-axial view of the skull of a patient who suffered intellectual impairment following a severe injury, the only other signs of which were anosmia and a crack radiating posteriorly from the foramen magnum.

spinal-fluid pressure is not found. Within two months of the injury, the spinal-fluid changes, if any, have vanished and are no longer of value in assessment. It is worth noting, however, that anosmia is frequently found as the only organic sign, associated with the severer degrees of intellectual impairment, apparently because blunt injuries, over the occiput in particular, result in severe cerebral commotion and at the same time cause tearing of the olfactory filaments. A vertical fissure in the occipital bone, radiating up from the foramen magnum and seen only in axial view (Fig. 7), may be present with the anosmia.

Ancillary methods, such as air encephalography (cisternal method) and electroencephalography, have served to clarify our ideas by lending objective evidence of damage to the cerebral structure. The second of these was used routinely, and the first in all difficult assessments and many others. Both methods suffer in their effectiveness because the slighter changes that can be thus demonstrated are also found in patients without head injury. Only rarely were they decisive in estimation of the patients who were difficult to assess by other

means. Conversely, defined change in either method alone, sometimes in both, could be consistent with successful return to duty if clinical considerations indicated it (Case 4).

Intellectual status alone is likely to give a false impression of general cerebral defect in cases in which aphasia has complicated a left-sided parietal or frontal focal lesion. Mild confusion may then impair all general intellectual function up to a late stage in recovery, but with much better ultimate prognosis than after a corresponding disturbance due to general injury. Special tests are necessary to elicit the special nature of this disturbance of function. In early convalescence, electroencephalography indicates the limited nature of

FIGURE 8. General P.

These are anteroposterior and lateral views of the skull of a patient in whom severe persistent dysphasia occurred following a blunt, nonpenetrating left temporal injury with skull fracture. Air encephalography shows a great widening of the frontal and temporal horns of the left ventricle.

brain damage in these cases, and as the localized electrical disturbance fades away, cisternal air encephalography begins to show the ventricular distortion due to the localized frontal or parietal atrophy (Fig. 8). An even, generalized dilatation of one ventricular horn caused by mild loss of brain substance following contusion (Stevenson⁴

and Greenfield⁴²) is of better prognosis than the peaked, tentlike traction defect due to an epileptogenic cerebrodural scar of the type described by Penfield.¹⁰ The former condition is by no means incompatible with return to duty, although a period of four to six months may be required before full efficiency is gained. In men and officers with long service, special qualifications and reasonably good nervous constitution, the decision that treatment should be persevered with for this period rests on a careful study made in the early stages. Such a decision in a military hospital concerns the need for avoiding the blocking of beds by patients who will never be acceptable for further duty. The accuracy of forecast in these cases depends on ability to eliminate a general intellectual defect in the presence of a focal lesion. It is necessary to distinguish the more diffuse types of dysphasia (amnesic dysphasia) from true residual aphasia, and likewise the recoverable kinds of monoparesis and hemiparesis, if accurate prognosis is to be achieved.

In thus presenting the clinical criteria on which the organic type of post-traumatic general cerebral syndrome is judged, some general considerations emerge. My experience has shown, as Symonds⁴³ had long maintained, that many patients labeled "post-concussion neurosis" or "compensation neurosis" in civil practice have in fact suffered severe cerebral injury as gauged by the above criteria. Most cases of so-called "pure traumatic neurosis" in a well-adjusted personality have been found to belong to this group.

Traumatic intellectual impairment may coexist with local cranial, facial or cerebral injury or with frank neurosis. The gravity of the general cerebral disorder in addition to such complications may have been apparent in the initial illness. Months after an injury about which adequate data are lacking, and for which the patient has a prolonged true amnesia, it may be extremely difficult to decide whether concussion did not in fact merge with contusion, hematoma, fat embolism or similar complications. Records of the duration of coma and the presence of aphasia, hemiplegia and so forth are difficult to obtain from field hospitals, but are so vital in the subsequent medical history of the soldier or airman that a special field card for head injuries was devised, with a simplified check system for rapid use in the field. The most urgent decision, however, is whether or not intellectual impairment is the substratum of the patient's present symptoms. If it is, improvement is obtained only by readjusting the patient's life to his disability.

Thus, I am not convinced that the cause of persistent organic disability lies in edema or other dis-

turbance of fluid balance, or in adhesions of meninges (epilepsy excepted). Evidence of persistent paralysis or, more commonly, of intellectual impairment, is regarded as the essential factor.

NONORGANIC FACTORS

A large group of cases with a disability syndrome that is labeled "psychoneurotic" remain to be discussed. Many of these present the post-traumatic general cerebral syndrome following trivial injury. The characteristic headache usually develops only after an interval that may be of day or longer, perhaps weeks. There is often a trace of injury, intellectual deficit, abnormal electroencephalogram or other change at any stage. A carefully taken history, however, elicits evidence of nervousness and anxiety, especially fears of serious consequences to health or to ability to continue earning.

A severe emotional reaction at the time of injury commonly occurs. Prolonged insomnia is its most reliable index. This immediate emotional reaction is not to be confused with the later emotional upheaval when, after severe injury, the patient first develops awareness of his calamity.

The disabling symptoms do not differ from other forms of anxiety neurosis except that headache is a prominent symptom. It is usually dull, generalized, steady and persistent, little or not at all relieved by rest, as in simple anxiety or depressive illness. In a small proportion of cases about one tenth, headache and dizziness on bending or on exertion, exactly comparable to those seen in the post-traumatic syndrome with severe brain damage, make their appearance. Schilder and others have suggested that the prominence of headache as a psychoneurotic reaction to head injury is related to a consciousness of the head or to ego. I believe that in the true syndrome some as yet undefined physiologic mechanism is at fault. Common association of the post-traumatic syndrome with poor physical development and with vasomotor instability, such as pallor and faints, often antedating the head injury, suggests a common background. It is remarkable that such a syndrome should respond to psychotherapy, and it is therefore concluded that it can be a psychoneurotic manifestation. Intolerance to alcohol, a well-known aftereffect of organic cerebral damage, also occurs in some purely psychoneurotic cases after trivial head injury. Headache may coexist with or be replaced by simple anxiety, fear, depression or hysterical fugues or blindness.

Psychoneurotic types of reaction to head injury are usual in mild mental defectives and psychopaths. Such persons suffer unduly prolonged disability from head injury; usually, the post-trau-

natic syndrome is a sign that their adaptation to the stresses of the world, already precarious, is easily disturbed by such an event as head injury. In civilian practice, morons and aged persons are also more sensitive to disturbance of an already precarious equilibrium.

An interesting variety of the psychoneurotic type of syndrome is that seen after repeated injury, such as occurs when a dispatch motorcyclist—in peace time a performer in "dirt track" racing in which he had sustained a number of head injuries without persistent effect—breaks down following a further relatively mild head injury. The mechanism is again that of loss of adaptation to stress. A predisposed temperament, carried through a series of events by a general optimism, eventually loses adaptation following a further trauma in the face of added anxiety but no greater actual danger or damage. This is to be distinguished from the condition of one who is "punch drunk," clearly an organic syndrome of cumulative kind.

It must again be emphasized that patients suffering from true traumatic intellectual impairment may break down in a psychoneurotic manner. If the original head injury was at all severe, the greatest care must be taken to exclude this possibility. If such impairment exists, the disorder is labeled 'organic,' for although the symptoms may respond rapidly to psychotherapy, no lasting relief can be obtained without adjustment of exertions and responsibilities to the level of lowered general capacity.

Disturbances variously labeled 'black-outs' and 'loss of memory' are extremely common during convalescence from head injury, and differ in degree, from brief periods of behavior, not remembered owing to lack of concentration, to hysterical fugues, which are usually motivated by some anxiety. These disturbances are usually on a functional or psychoneurotic basis, but experience has shown that in a few cases such dissociated states were associated with true epilepsy attributable to the brain injury. Thus, traumatic epilepsy, which causes dissociation (automatism), may facilitate a motivated amnesic wandering in a patient also subject to anxiety. In such cases, the usual treatment for psychoneurosis is naturally ineffective unless the organic substructure is recognized and also receives treatment.

In Britain, the diagnosis of 'shell shock' is no longer made following the findings of a special committee in 1922,¹⁴ and of another in 1940,¹⁶ which recommended that the condition be resolved into its psychoneurotic or organic constituents. The common 'shell shock' was none other than the psychoneurotic type of post-traumatic reaction. The group also included some cases of residual intel-

lectual impairment from severe general brain injury as it is now recognized, and some of more obvious anxiety neurosis. Such disorder resulting from bomb or shell blast does, in fact, still occur, and close examination of the amnesia reveals its hysterical properties. In supposed cases of concussion due to blast, the patients turned out either to be of this type or to have suffered a secondary injury to the head from being thrown against a hard object, or struck by falling masonry, as in Eden and Turner's²⁰ cases.

The following case is an example of hysterical amnesia.

CASE 7 Private A C L, aged 29, survived several severe bombings without symptoms. He had an excellent family personal and occupational history. On May 30, 1940, a shell dropped within several yards of him in a trench. He remembered nothing for 3 hours, and recovered consciousness walking in a wood crying like a baby (his own words) and shaking all over, about ¼ mile behind the line. He had a severe headache but when examined at a dressing station had no sign of injury. He was transferred to a hospital, and continued to suffer from severe headaches worse in the mornings, and severe insomnia. He trembled on hearing an aircraft and kept thinking of a friend of his who had earlier been killed. The symptoms persisted and on admission under my care he was found to have no sign of injury, normal anxiety films and an excellent intellectual status. The amnesia was found under Amytal narcosis to be hysterical and with simple psychotherapy all symptoms rapidly resolved and the patient returned to duty without relapse.

The type of anxiety varies from patient to patient. In the airman, conscious or unconscious fear of further flying accidents is a natural anxiety that must always be taken into account, no matter how trivial the injury or how obvious the structural damage. The loss of an eye, or of vision in one eye conditions anxiety regarding the remaining eye. A gap in the skull, itself reasonably safe from damage, except by sharp objects, is a source of fear to the owner despite the firmest assurance to the contrary. Unreasonable fears are usually based on the gravity with which some uninformed physician has at some time viewed the scar or injury. Those who "take a grave view" and display to the patient some uncertainty regarding the ultimate outcome, little know how lasting a fear is implanted in the patient's mind, or how disabling and difficult to treat the consequences may be. Often, the sole reason for an anxiety neurosis turns out to be some casual conversation with a friend who remarked that he knew of another who had suffered a similar injury and "never got over it." This common explanation of secondary anxieties resulting from head injury is, I am sure, the basis for the immensely superior results obtained when the convalescence from head injury is managed

throughout by a thoughtful physician well aware of the psychologic dangers besetting his patients, and when all patients with recoverable disability are early segregated from the severer ones.

With some experience, it is soon realized that a positive constitutional nervous history, in addition to a poor response to intensive, although simple, psychotherapy, will prevent any return to military duty. It is, however, often of value to have a different psychotherapist attempt treatment for a brief trial period before discharge from the service is advised, for psychotherapy is an intensely personal affair. Decision is nevertheless usually made rapidly in the severe case.

The greatest difficulty arises in the *borderline case*—the patient who makes a good response to treatment but is liable to relapse in the stress of battle. Such difficulties in England were complicated by the fact that there was no really "safe area" to which a soldier or airman could be transferred for a period. Relapse could occur as readily with bombing as with service overseas. No matter how many relatively minor or routine posts there may be in any army battalion or air-force ground staff, a man subject to relapse is always a liability to his commander. This was abundantly clear in the fighting in Belgium, where war-weary troops literally carried their neurotic comrade with them.

In the borderline cases, the critical factors in head-injury neuroses are exactly the same as those in other war neuroses with the addition of anxiety concerning the possibility of brain damage. Lewis and Slater⁴⁷ have recently studied the relation of various factors to prognosis in neurosis in soldiers, comparing two groups of 150 men, all considered by medical boards to have made full recovery. One group was successful in returning to full military duty for at least three months, the other group having been fit and returned to duty but having relapsed sufficiently to require subsequent discharge from the service. These authors list twenty attributes, which are as follows: *family history of nervous or mental breakdown*, poor school record, unsatisfactory childhood, *unsatisfactory work record*, *previous psychopathic traits or nervous breakdown or symptoms*, time in hospital, *dislike of Army life in past*, keenness to return to Army, military stress (for example, Dunkirk), adequate external anxiety (domestic or financial), disillusionment, physical factors, conversion symptoms, *querulous hypochondriasis*, depressive symptoms, anxiety symptoms, *amnesic episodes*, surly or *paranoid attitude*, fits and faints. The italicized factors are shown to operate powerfully in favor of relapse, but the analysis also shows clearly that no one of these factors is alone sufficient for unsatisfactory

return to duty; it is any combination in this series that counts. Exposure to severe military stress and keenness to get back to duty are shown to operate clearly in favor of successful return to full duty. This is entirely in accord with my own experience with head-injury neurosis. However, to the italicized group, I should add disillusionment, anxiety about brain damage and fits. The decision to return to duty in borderline cases depends on the number of these factors, their duration and the nature of the stress that precipitated them.

Much has been made of ventricular dilatation demonstrable by air encephalogram in cases of head injury since attention was first drawn to its occurrence by Bielschowsky.³⁰ It has been held to demonstrate an organic basis for psychoneurotic symptoms.^{48, 49} My experience has led to the opinion that, although it means loss of cerebral substance and damage to axis cylinders and myelin,⁵⁰ ventricular distortion by no means settles the nature of the patient's disability. As in Case 3, it is frequently present when no persistent disability has occurred, and also in many other cases in which the disability is demonstrably a psychoneurosis and is amenable to treatment. This may also be true of persistent electroencephalographic abnormality, which must be considered in relation to other factors, such as nervous constitution and intellectual impairment, before it can be regarded as significant.

It is of considerable interest to compare the conclusions reached by us with the excellent clinical analysis of civilian compensation cases made by Schaller.¹⁷ Whereas our findings agree in broad essentials with his two clinical syndromes (post-traumatic concussion state and post-traumatic psychoneurotic state), which are common and characteristic, no single clinical feature is diagnostic, and every variety of intermixture can be found. Moreover, the psychoneurotic patient is often anxious to resume occupation, and more frequently exhibits difficulty in concentration, precise symptomatology and tendency to improve than the patients in Schaller's series. Our organic cases also showed more liability to functional overlay, more frequent headache and less aggressiveness than those of Schaller. Although the extreme clinical syndromes are characteristic, no single clinical feature is diagnostic. Nor do we consider the conception of "post-traumatic general cerebral syndrome" of Foerster¹⁴ as a clinical entity of practical value. Of such a variable series of clinical pictures as those persisting from head injury, no two or three broad divisions are possible. Instead, each case should have separately estimated organic residua and psychoneurotic symptoms.

PSYCHOSIS

Frank psychosis resulting from head injury is extremely rare. Mania, deep depression or schizophrenia (1 of each in the 400 cases) may be precipitated by the general disturbance of the injury in a person with a strong predisposition. More commonly, the phase of confusion during recovery from a severe injury may be colored by elation, depression or hallucinatory experience. When confusion is prolonged, this phase may also be prolonged for weeks or months, but with a steady tendency to recovery.⁴³ A type of phonographic loquacity associated with catatonia was seen in 2 cases in this period.

Changes in personality and outbursts of irritability are not uncommon (9 in the 400 cases), but there is usually some evidence of instability and swinging of mood before the injury. Obsessional traits may become extremely pronounced. Such changes are therefore regarded as usually being psychoneurotic, and are not directly comparable to the more complete change in personality seen sometimes in children after head injury.

CULPABILITY

The greatest emphasis must be placed on the frequent combination of structural damage and psychoneurosis. It is impossible to keep these two pigeonholes entirely separate. It is both unjust and bad treatment to regard conscious or subconscious malingering as the only alternative to grave damage to the brain. Pure malingering is extremely rare, and its inconsistencies relatively easy to entrap. Psychoneurotic behavior motivated by dislike of military life is commoner. But most post-traumatic neuroses, especially the psychoneurotic factors that prolong disability from head injury, are deeper than this. Most commonly, they arise from a combination of natural anxieties with prolonged war stress. These and constitutional liabilities are beyond the patient's realization or control. Although careful psychiatric selection of draftees will minimize disorders due to constitutional psychoneurotic liability, it cannot entirely prevent them. Even in air-force pilots, very highly selected in this respect, the constitutional factor was often elicited only by prolonged investigation after the disability had arisen.

Whereas psychoneurosis has not the stigma it once had, some further education of the general lay public is necessary in this respect, for in many cases war trauma is in part or wholly responsible for prolonged total disability of psychoneurotic kind, incurred through truly courageous and heroic acts. That it should occur very often in the course of simple devotion to duty should not close one's eyes to its essential nature and thus erect a barrier

to efficient treatment. That the bravest man may develop a psychoneurosis through no fault of his own, particularly under circumstances of exhaustion and fatigue, was a fact well recognized as long ago as 1815 by Lord Wellington when he was consulted regarding a psychoneurotic casualty of the Peninsular War.⁵¹

When compensation is a factor, the issue should be fairly and squarely faced and decided forthwith. Compromise in this respect nullifies the effect of any kind of treatment. Once the issue is settled, in service as in civil cases, treatment should proceed, for the condition seldom subsides spontaneously.

TREATMENT

From what has been said, it should be clear that head injury is by no means a clinical entity for which a cut and dried line of treatment can be prescribed. This is as true of the persistent after-effects as of the acute stages. Each case must be treated according to its particular merits. When the relative gravity of bony, cerebral and emotional factors and the effect of any foreign bodies that may be present have been estimated, the line of treatment to be pursued and its likelihood of success become clear.⁵² Objective records, such as ventricular air studies and electroencephalography, are extremely valuable but seldom achieve a short cut to clinical evaluation.

It is not considered possible even to list a particular treatment for any particular symptom, for any symptom may have either psychoneurotic or organic emphasis and, if organic, a focal or generalized cause. Thus, traumatic epilepsy may be related to a transient effect of a single defined scar or diffuse degenerative process, may have an identifiable removable cause, or may be only the awakening of a latent liability by a generalized physical effect. This is also true of paralysis, or visual disorder, when only experienced, trained observers can give an estimate of the degree of unrecoverable disability. It is not enough to say that a patient cannot read because he has a visual-field defect. One must know whether that particular defect does in fact interfere with reading and, if so, whether a particular method of training can bring improvement, and if not, how to deal with the psychologic difficulty that blocks recovery. In the armed forces, it is further necessary to be able to give some estimate of the prognosis regarding ultimate resumption of duty, and the time likely to be consumed. The problem is then often complicated by the fact that the limitation in capacity may not enable the patient to continue holding his former appointment, and intimate knowledge of the service is required to determine whether such limi-

tation is possible in other duty carrying the same rank, and, if not, whether the necessary change in status is likely to be the cause of a relapse.

The treatment of surgical complications is one of which the neurosurgeon can more properly speak. For all types of organic paralysis, such as spasticity, loss of sensation and of vision, and ataxia, exercises are more valuable than any other form of therapy and, in addition to experience, enthusiasm and adaptability are of the greatest benefit in the physiotherapy division. Enough has been said to indicate that even the most apparent spastic hemiplegia should be carefully assessed for psychoneurotic and other complicating features before it is assumed that no further recovery is possible.

Psychologic treatment is most effectively undertaken and supervised by those who take the original psychiatric history, for the initial psychologic rapport and understanding thus obtained is a good starting point. For hysterical amnesia, hypnosis and prolonged association are effective but time consuming, and most experienced workers shorten the procedure with brief Amytal narcosis, to break down inhibitions and take a short cut to suggestive treatment. All anxieties are fully discussed, and reassurance given. Encouragement and supervision in graded occupation and exercise are necessary. Communication with the soldier's commanding officer may be needed in matters of pay or discipline, and with the Red Cross or other social services or relatives for the patient's family troubles.

All cases of structural injury to the brain and skull require such prolonged convalescence that, unless some interesting diversion is provided, psychoneurotic complication or ordinary discouragement is liable to occur. Here is the place for occupational therapy,—leatherwork, basket making, bookbinding, wood carving and so forth,—which was early developed in our hospital and assumed a most important place in therapy. It should not be confused with rehabilitation, and nothing is worse than for these patients to get the idea that organized carpentry is to refit them for civilian life. They should recognize from the first that they are to return to duty, and should regard the treatment as a pastime. The best instructor gives most time to the clumsy performer, for it is he who is deriving most benefit. Others are apt to spend too much time with their more successful pupils, forgetting that they either no longer require instruction or should be promoted to more strenuous activity. The subject has recently been discussed by Jefferson et al.⁵³

For the final stages of convalescence, a rigorous schedule is required. This was carried out in a special convalescent branch of the hospital with a resident medical officer. There was also a weekly visit and an interview of each patient by the med-

ical specialists of the parent hospital. Graded physical activity and exercise, especially stooping, leading up to heavy digging, sawing wood, swimming, football and boxing, were essential. Only in this way could a disappointing relapse be prevented on return of the soldier to active military duty.

Throughout this performance, it is essential for a physician who knows the whole circumstances of the case to supervise progress. Time must be given to regular discussion of all problems with each patient. Only then is it realized how small problems crop up from day to day, and how much individual attention to detail counts. And this extends, as will be explained below, to the personal and family affairs of the man.

The medical officer soon learns to recognize the "catastrophic reaction" (Goldstein¹²)—the gesture of failure by sudden abandonment of co-operation on the part of the patient. This requires patient and firm encouragement, the right mixture of sympathetic understanding and unyielding pressure, which is the most difficult yet essential feature of psychotherapeutic management to teach the younger medical officers. Its successful accomplishment springs from correct appraisal of the causes of breakdown.

The most valuable single factor in the management of head injury is undoubtedly that which might be called prophylactic psychotherapy. This is the affair of the ordinary physician or medical officer. Optimism is often said to be the essence of psychotherapy. Whereas this is surely true of nervous conditions in general, its wholesale application to head injuries is nearly as detrimental as undue pessimism. There is nothing more infuriating and discouraging than to be expected to achieve what is not possible. The successful management of head injuries therefore requires knowledge of what might reasonably be expected of the patient. To get a moderately severe head case up in the third week after injury brings the same troublesome sequelae as keeping a very mild case lying flat for four weeks. The first is discouraged by failure and takes a long time to get over the reaction; the second is convinced that some vital damage has occurred and will be anxiously on the *qui vive* for catastrophe for a long time afterward. The nature of the man and the severity of the injury must be taken into account. Insomnia and anxiety indicate underlying emotional tension. Regular discussion of difficulties, reassurance and encouragement to further performance are the keynotes of success. They are not time consuming, and the right kind of discussion for five minutes each day can accomplish more in the early stages than whole days of psychotherapy can correct at a later date. One of the commonest causes of relapse is the at-

itude taken by relatives, the family doctor or the medical officer of a convalescent home. Time and again, a patient who has progressed favorably has been allowed home to convalesce, and the first time he has had a mild headache has been taken by anxious relatives to the family doctor, who, hearing that he has had a head injury, insists on complete and prolonged rest in bed (instead of planned activity and less excitement). This strong suggestion is too much for many patients, who relapse forthwith. For this reason, a brief spell of active duty before a leave of absence is usually advised.

CONCLUSIONS

In conclusion, it is emphasized that the peculiar mixture of trauma and emotional shock that constitutes all war (and most civil) head injuries retains traces of both features throughout the convalescent period. Too frequently, emphasis is laid wholly on either structural damage or psychoneurotic state, with consequent failure to achieve the best results from treatment of both. Although particularly evident to the trained neurologist by reason of his familiarity with both functional and organic nervous disorders, the proportions of the mixture should be evident to anyone who takes time to sum up the pretraumatic nervous constitution and personality, the severity of the general brain injury, the residual intellectual and physical state, and the nature and degree of persistent anxiety. It is from lack of full appreciation of such factors that disappointment in the results of treatment arises. It is maintained that intensive effort along these lines not only will conserve and rapidly restore to duty officers and men the services can ill afford to lose but also will substantially reduce the great bulk of persistent disability that became a national calamity after at least one previous war.

The diagnostic and prognostic limitations of abnormalities in air encephalograms and electroencephalograms are discussed, and the important conclusion reached that some persistent defects in these are compatible with recovery without any disability. It is maintained that the key to most organic disability is defective intellectual function.

No single test will alone demonstrate a hopeless prognosis.

I am greatly indebted to my commanding officer, Lieutenant Colonel G O Chambers, MC, RAMC, for the privilege of making these comments and to Air Commodore C P Symonds, RAFVR, whose unfailing energy and advice was the mainspring of the project, both in its inception and throughout its development. Finally, I should like to mention my associates, Majors W R Russell, W Reynell and M McArdle, of the RAMC, and the group of junior officers, without whose devotion, patience and care, especially in intelligence testing, the results that were achieved would not have been possible.

The patient was transferred to this hospital 7 weeks after the onset of fever and extreme weakness. On examination, she appeared pale, sallow and drowsy, she was scarcely able to move in bed. Her temperature was 102.5°F, the pulse 126, the respirations 18, and the blood pressure 102/40. No petechiae, purpura or telangiectases were found, although flame-shaped hemorrhages were observed in the fundus of the right eye. The lungs were clear. The heart was of normal size, a soft systolic murmur was heard over the pulmonic area. The spleen descended 5 cm below the costal border on inspiration and extended medially to the midclavicular line. The liver edge was palpable at the costal border. The abdomen was tense and distended but not tender. There was slight edema of both ankles. No clubbing of the extremities or enlargement of lymph nodes was present. Examination of the pelvis, rectum and nervous system revealed no abnormality.

Of chief interest were the blood changes, shown in Figure 1. The initial white cell count was 10,100, with 61.5 per cent neutrophils, 13.5 per cent band forms, 0.5 per cent eosinophils, 1.0 per cent basophils, 5.0 per cent small lymphocytes, 6.5 per cent large lymphocytes, 6.5 per cent monocytes, 0.5 per cent young monocytes, 1.0 per cent myelocytes and 4.0 per cent metamyelocytes. The hemoglobin was 23 per cent (Sahl—36 gm per 100 cc.). The red-cell count was 1,000,000, with 31 per cent reticulocytes. In addition, there were 55 nucleated red cells per 1000 white cells. The red cells varied greatly in size but little in shape, the majority being macrocytes, there were no fragmented cells. The hematocrit reading was 12.2 per cent, the mean corpuscular volume 122 cubic microns, and the mean corpuscular hemoglobin concentration 29.4 per cent. A wet preparation of red cells showed no evidence of sickling in 24 hours. The fragility of the red cells in hypotonic salt solutions was significantly increased.

The plasma bilirubin was increased to 1.73 mg per 100 cc. (normal, 0.2 to 0.7 mg)⁵ The serum contained 60 mg of free hemoglobin per 100 cc (normal, trace to 50)⁶ The plasma protein amounted to 5.5 gm per 100 cc albumin 2.89 gm, globulin 2.36 gm and fibrin 2.49 mg. The blood nonprotein nitrogen ranged between 26 mg per 100 cc on the 1st day and 29 mg on the 16th day. The icteric index varied from 15 to 25 units. On the 1st and 12th days, the Donath-Landsteiner Test,⁷ the hemolysis test with acidified serum⁸ and the test for autohemolysis⁹ were all negative. Autoagglutinins were insignificant, being present in only a 1:8 dilution at 0°C.⁹

Repeated specimens of urine were acid, had a specific gravity varying from 1.022 to 1.012, showed a + test for albumin and contained many white cells, but no red cells, bile or hemoglobin. A culture was positive for *Escherichia coli*. From a portion of a 24 hour sample, the urobilinogen excretion was estimated to be 5 mg per 100 cc.¹⁰ Bile was present in the stools, occult blood was absent.

In the first 5 hospital days, the patient received four transfusions, each averaging 600 cc of blood. On the 6th day, the spleen was removed. Red cells obtained from the splenic vein blood at operation were just as fragile as those previously tested (Fig 1). With the aid of transfusions, the red-cell count rose to 4,000,000 following the operation, but within 6 days fell to 700,000. The nucleated red cells rose from 55 to 175 per 1000 white cells, while reticulocytes fell from 30.8 to 4.4 per cent (43,800 per cubic millimeter). The white cell count increased from

10,000 to 79,000, with 1 per cent myeloblasts. The platelet count, originally 200,000, reached 900,000. The plasma bilirubin rose from 1.7 to 3.7 mg per 100 cc, and free hemoglobin persisted in the serum, although in lesser amounts. The fragility of the red cells in hypotonic salt solution increased still further.

The patient received three blood transfusions following operation, but even these failed to check the progressive anemia. On the 12th hospital day, x-ray films of the chest, which were normal on admission, demonstrated infiltration of the right supraclavicular region and fluid at the right base. No organisms grew out of a blood culture taken on the tenth day. She received 90 gr of sulfapyridine in divided doses by mouth on the 13th and 14th days. Because of the excessive nausea and vomiting that ensued and because of a falling red-cell count, this medication was discontinued. The temperature continued to spike to 103°F, and edema appeared in the legs. The patient died on the 19th hospital day.

The spleen, removed at operation, weighed 710 gm. Its capsule was smooth, its consistence firm. On section, the cut surface was dark red gray with several scattered yellow soft areas varying from 0.6 to 4.0 cm in diameter. Neither the Malpighian corpuscles nor the trabeculae were prominent. Scanty blood scrapings were obtained from the surface. The splenic artery and vein were not remarkable. On microscopic examination, the Malpighian corpuscles were found to be fairly well preserved. Fibrosis of the pulp was diffuse and moderately extensive. Numerous clumps of myelocytes with rare adult granulocytes were prominent. Many foci of red cell formation were present. Megakaryocytes were moderately numerous throughout the section. Many of the macrophages seen contained hemosiderin. The histologic picture was typical of myeloid metaplasia, and in no way suggestive of that seen in hemolytic jaundice.¹¹

Autopsy (A40914) The body was examined 3 hours post mortem. Type 3 pneumococcal lobar pneumonia was found, as well as a recent infarct of the right upper lobe of the lung. The infarction was embolic from an ante-mortem blood clot of the right femoral and saphenous veins. There were icterus, pallor, pulmonary edema, peripheral edema, bilateral hydrothorax, hydropericardium, hepatomegaly (1810 gm) and hyperplasia of the vertebral, sternal, costal and femoral marrows. The tibial marrow was composed entirely of fat.

Microscopically, the liver and kidneys showed an abundance of hemosiderin but no evidence of myeloid metaplasia. A small degree of myeloid metaplasia was present in the scar tissue at the site of splenectomy and in one cervical lymph node. The vertebral, sternal, costal and femoral bone marrows were hyperplastic in both the red cell and white cell series. The usual number of megakaryocytes was found. Hyperplasia of the red cell series only slightly exceeded that of the white-cell series. Many immature forms of both series were observed, although normally matured cells were by no means absent.

DISCUSSION

Excessive hemolysis of red blood cells occurred in this patient, as evident from the severe and persistent anemia, hemoglobinemia and bilirubinemia in the absence of bilirubinuria. The pathogenesis of this hemolysis was sought among the known causes of hemolytic anemia.

First, a search was made for hemolysins. Tests for Donath-Landsteiner hemolysin⁷ and autohemolysin⁸ were negative. Hemolysin arising from the spleen⁸ was excluded by the fact that the signs of hemolytic anemia persisted after splenectomy. There was no evidence of transfusion reactions or of an infection by such hemolytic organisms as the hemolytic streptococcus or *Clostridium welchii*.¹² Secondly, agglutinins were looked for, because hemagglutination can, as Ham and Castle¹³ have demonstrated, produce hemolytic anemia. Tests for autoagglutinins⁹ were negative. No unusual isoagglutination was observed when the patient's blood was cross-matched with those of the donors.¹⁴

A third cause of hemolytic anemia is an abnormality of the erythrocytes. The origin may be extrinsic, as in malaria and Oroya fever, or intrinsic to the erythrocytes, as in paroxysmal nocturnal hemoglobinuria. That the patient's red cells did not hemolyze in acidified serum of the same blood group excludes the last diagnosis.⁶ Failure of the red cells to sickle eliminated the possibility of sickle-cell anemia; however, the morphology of the erythrocytes was suggestive of Cooley's anemia.¹² This diagnosis was not tenable because the patient was not of Italian stock, because her family gave no history of anemia, but chiefly because her red cells were more fragile than normal. Finally, examination of blood smears disclosed no organisms to suggest the diagnosis of malaria or Oroya fever.⁹

The next cause of hemolysis considered was some noxious agent. The patient could recall no exposure to the fava bean¹⁵ or lead.¹² On the other hand, the family stated that the patient had used much Energine, which contains carbon tetrachloride, to clean her shoes. Furthermore, her husband used to make model airplanes in the bedroom and employed a glue that probably had a benzene base. At the commencement of her illness, the patient received 40 gr. of sulfanilamide. It is unusual, however, for sulfanilamide¹⁶ to cause a hemolytic anemia that persists despite transfusions for two months following withdrawal of the drug. The effect of sulfapyridine given to the patient on the thirteenth hospital day is more difficult to appraise. That extreme hemolysis occurred in the five days after sulfapyridine therapy is evident from the decrease in the red-cell count from 2,500,000 to 700,000. But this rate of destruction is comparable with the drop from 4,000,000 to 2,500,000 during the two days preceding sulfapyridine therapy. Therefore, sulfapyridine cannot be considered a significant hemolytic agent in this case.¹⁷

There was an extreme increase in the fragility of the red cells. Congenital hemolytic jaundice was excluded by demonstrating that both parents had completely normal blood values. The cause of the abnormal fragility in this patient cannot be stated, although it is clear from the recent work of Ham and Castle¹³ that increased fragility of erythrocytes predisposes to an abnormal degree of hemolysis. To recapitulate, the increased fragility of red cells was the only evidence found in this patient for an abnormal mechanism of their destruction.

What role did the spleen play in this hemolytic anemia? Except for the finding of myeloid metaplasia of the spleen,* the anemia had the characteristics of acute hemolytic anemia: vigorous erythropoiesis, as indicated by high concentrations of reticulocytes before operation; excessive hemolysis, evident from anemia; hemoglobinemia; and bilirubinemia. Because splenectomy did not diminish the already increased fragility, the spleen was clearly not the cause of it. On the other hand, the failure of the reticulocytes to increase after splenectomy as the anemia progressed suggests that the spleen, before its removal, was an important organ of erythropoiesis. The low postoperative reticulocyte count might be interpreted as a sign of toxic inhibition of red-cell production by sulfapyridine. Against this interpretation stand the observations that sulfapyridine does not inhibit reticulocytosis and that when a hemolytic anemia is produced by sulfapyridine therapy,¹⁸ inhibition of white-cell and platelet production, often associated with toxic anemias, did not occur. Hence, the post-splenectomy disappearance of reticulocyte response probably means that the removal of the spleen deprived the patient of an important erythropoietic organ—a conclusion consistent with the experience of other investigators.^{2, 3}

SUMMARY

A case is reported of acute hemolytic anemia with myeloid metaplasia of the spleen, in which splenectomy was performed.

Increased erythrocyte fragility was the only evidence found of an abnormal mechanism of destruction of red blood cells. The cause of this increased fragility was not discovered. Splenectomy did not cause decrease in the fragility.

The disappearance of signs of blood production subsequent to splenectomy indicates that the spleen was, in this case, an important blood-forming organ, the removal of which probably reduced the erythropoietic capacity of the body resulting in a fatal anemia.

*Dameshek and Schwartz⁵ found myeloid activity in an impression smear of the spleen of acute hemolytic anemia, but they did not record the pathologic findings in this organ.

DURAL CONSTRICTING RING WITH CERVICAL PROTRUDED INTERVERTEBRAL DISK

Report of a Case

CAPTAIN WALTER G. HAYNES, M.C., A.U.S.*

THE incidence of the Arnold-Chiari malformation at the foramen magnum, associated with syringomyelia or hydromyelia of the upper cervical cord, has been noted by a number of authors, notably Gustafson and Oldberg,¹ D'Errico,² Russell and Donald,³ Rosenblath⁴ and Lichtenstein.⁵ All these authors mentioned the occurrence of syringomyelic cavities in association with the true Arnold-Chiari malformation. Lubin⁶ thought that chronic adhesive spinal arachnoiditis might cause intramedullary cavitation. Mackay⁷ reported a case of cervical arachnoiditis with cavitation and implied a causative effect. Schwarz⁸ believed that syphilitic pachymeningitis cervicalis also could cause cavitation. Gustafson and Oldberg mentioned the incidence of the syringomyelic cavity associated only with a dural constricting ring which was, in their cases, accompanied by a deformity of the foramen magnum.

Although there were no positive statements by any of the authors mentioned to the effect that this foramen magnum deformity or the dural constricting ring contributed to the formation of the cyst, the general implication throughout their articles was that a dural ring constricting the cord at the level of the foramen might have contributed to the formation of the cyst. It was further intimated that this could be caused by interference with the vertebral artery at the foramen or interference with the circulation of cerebrospinal fluid through the foramina of Magendie and Luschka,

thus causing either hydromyelia or hydrocephalus or both. These conditions would be more apt to be caused by the complete Arnold-Chiari malformation, with a herniation of the cerebellar tonsils to occlude completely or partially the fluid passageway. Hassin,⁹ however, spoke of the prevalence of arachnoid and dural reaction at the level of and above the syringomyelic cyst, and this condition he considered to be secondary to the syringomyelic cavity rather than a causative factor. This view is also borne out by Schlesinger,¹⁰ who reported the occasional findings of dural and arachnoid adhesions at the level of or above the cyst. Hassin¹¹ maintained, furthermore, that the fact that meningeal changes in syringomyelia are not always mentioned or emphasized by authors indicates that they cannot be a primary factor, since, if such changes do not exist, they cannot produce a cavity or any other process in a spinal cord. On the contrary, he believed that a long-standing or advanced syringomyelic cavity or other space-occupying lesion of the cervical cord might cause meningeal changes.

This latter view is favored by the following report of a patient in whose case the space-occupying lesion at the level of the fifth cervical vertebra was not a syringomyelic cyst but a protruded intervertebral disk. This disk was accompanied by an arachnoid reaction, which surrounded it, extended upward and culminated in severe arachnoid proliferation, dural thickening and the formation of a dural constricting ring at the level of the foramen magnum. Complete roentgenographic studies re-

*Chief of the Neurosurgical Section, Lovell General Hospital, Fort Devens, Massachusetts.

vealed no evidence of platybasia or upper cervical malformation, and none was found at the time of operation. It must be emphasized that this was not a case of true Arnold-Chiari malformation, and no argument is advanced in this report to the effect that a space-occupying lesion could cause an Arnold-Chiari malformation.

CASE REPORT

A 36-year-old man entered the Lovell General Hospital on October 24, 1941. His complaints at that time were confined to soreness in the right arm, which he had first experienced 2 months prior to admission. The pain had been persistent, but was worse at some times than others, particularly when the weather was damp or cold. It had progressed to involve the entire upper extremity and radiated from the back down the arm along the ulnar side. The pain was usually dull and aching but was interspersed with many sharp, shooting pains which were made worse by coughing or sneezing. At another hospital, roentgenograms revealed a dislocation of the 5th cervical vertebra on the 6th. The patient was placed in traction, but since this made his pain worse, it was discontinued.

On admission, no history of injury to or about the vertebral column could be elicited. There was a long-standing history of loss of weight, cough and so forth, suggesting tuberculosis. There was also a history of prostatitis.

Physical examination revealed a thin, emaciated white man, but was otherwise negative. Neurologic examination of the cranial nerves was negative, except for a fine, sustained nystagmus on looking to the left. There was a slight loss of power of the right arm and leg. There was no anesthesia or hypesthesia. There was some tenderness on percussion of the 4th cervical vertebra. All the reflexes on the right side were markedly increased over those on the left side, with a sustained ankle and patellar clonus and positive Hoffmann, Chaddock and Rossolimo signs on the right. The cremasteric reflex was absent on the right, as were both abdominal reflexes. Roentgenograms taken in all positions were negative, and the previous report of a dislocation of the 5th cervical vertebra on the 6th could not be verified. Spinal puncture revealed evidence of an almost complete subarachnoid block, with an increased spinal-fluid protein and a positive Pandy reaction. Fluoroscopic examination of the chest revealed an old, healed cavitation in the apex of the right lung, which was interpreted to mean an old, healed tuberculosis. A prostatic smear revealed a few pus cells. The remainder of the study was entirely negative.

A diagnosis was made of either cervical arachnoiditis or a cervical protruded intervertebral disk at the 5th and 6th cervical vertebrae. A laminectomy was performed November 21, 1941. The operative note was as follows:

Under endotracheal ether, the usual subperiosteal exposure of the laminae of the 3rd, 4th, 5th and 6th cervical vertebrae was carried out. This exposure was unduly difficult because of increased vascularity; however, with the help of the Bovie unit, this was controlled until it became necessary to remove the spines and the laminae. A large plexus of dilated veins was found between the dura and each lamina, and every time a portion of the bone was removed, this plexus was torn, causing furious bleeding, which was checked with difficulty. Eventually, however, the dura was exposed under the laminae of the 3rd, 4th and 5th

cervical vertebrae. The dura was opened and there was immediately a large gush of yellow cerebrospinal fluid. This opening was extended, and a mass of arachnoid adhesions, which were diffuse and fine, was exposed. At the caudal end of the incision a bulging of the cord could be seen. The cord appeared large and flattened in this area, so that a syringomyelic cyst was suspected. The hypodermic needle was inserted between the posterior columns, and the area aspirated; but no cystic material could be obtained. The incision was therefore extended caudad to expose and remove the bone and to open the dura over the defect. It could then be seen that the bulge in the cord was not due to a cyst, but rather to a space-occupying lesion beneath the cord, which pushed it posteriorly. On gentle retraction of the cord by means of the dentate ligament, a fairly large herniated intervertebral disk was discovered at the interspace between the 5th and 6th cervical vertebrae, lying on the right side of the cord and compressing the roots emanating from the cord. This protrusion measured approximately 2 cm. and extended across the intervertebral-disk space almost to the other side. The ligamentum flavum was trimmed away and this area was decompressed. A catheter was then passed with ease over the obstruction. On attempting to pass a small catheter cephalad, however, another obstruction was met under the first cervical vertebra, so that the incision was then extended in this direction and the dura opened. Here was found a marked thickening of the dura and arachnoid with an actual constricting ring compressing the cord and causing a complete block in this area, just below the foramen magnum. No bone deformity could be found, although the foramen magnum was inspected thoroughly. This area was decompressed so far as possible, and the dura was left open so that a catheter could be passed with ease in this direction. Hemostasis was obtained with difficulty, and the wound was closed in the usual fashion. The condition of the patient at the termination of the operation was good.

Diagnosis: Protruded intervertebral disk at the 5th and 6th cervical vertebrae, with a dural and arachnoid proliferation to form a constricting ring at the foramen magnum.

The postoperative course was satisfactory until 2 months later, when the patient complained of a reddened, tender area in the incision line. This was opened and found to contain pus. Accordingly, the entire area was opened, cleaned out and allowed to granulate in from the bottom. This was accomplished without difficulty. The patient still exhibited pyramidal tract signs, which gradually disappeared. Five months later, he walked without a limp and had no pain, but still exhibited positive Rossolimo and Hoffmann signs on the right. There was no limitation of motion in the neck.

SUMMARY AND CONCLUSIONS

A case is reported in which a severe arachnoid and dural reaction at the foramen magnum was interpreted as being secondary to a cervical-cord space-occupying lesion, in this case a protruded intervertebral disk.

In the absence of platybasia or other bony deformity, a dural and arachnoid constricting ring

was found at the level of the foramen magnum, the reaction apparently starting at the level of the protruded intervertebral disk at the fifth cervical vertebra and extending cephalad, becoming very marked at the foramen.

It is suggested that, contrary to general opinion, the syringomyelic cavity below a dural constricting ring at the foramen magnum is not secondary to the malformation, but causes the dural and arachnoid reaction resulting in the malformation.

This report does not attempt to explain the syringomyelic cavity found in the cases of platybasia where the odontoid process has caused a dural reaction resulting in the same constricting ring

THE DIAGNOSTIC VALUE OF SERIAL MEASUREMENTS OF ALBUMINURIA IN AMBULATORY PATIENTS*

HARRY A DEROW, MD†

BOSTON

UNSUSPECTED albuminuria is frequently found in apparently healthy individuals. It is often difficult to decide whether or not this finding is indicative of organic renal disease. Many authors have attempted to evaluate the significance of such apparently incidental albuminuria.¹⁻⁶ Studies in ambulatory patients with albuminuria of the concentration of albumin in consecutive samples of urine voided over a period of twenty eight to thirty-four hours have yielded information of help in the differentiation of benign from pathologic albuminuria. The present report analyzes the findings in such cases, the studies will be continued for many years, additional data being obtained on these patients as well as on all similar ones who come to our notice.

MATERIALS AND METHODS

Three hundred and fifty-nine studies were made on 123 ambulatory patients. Twenty six of these patients had other signs and symptoms establishing the diagnosis of glomerulonephritis. Eight patients had pyelonephritis, 2 had lupus erythematosus, and 42 had primary arterial hypertension. In 45 patients none of the above diagnoses were made, patients with congestive heart failure, diabetes mellitus or certain diseases of the genitourinary tract were not included in this group.

The following printed form was given to each patient before the start of each study

Albuminuria Test

Before starting this test, secure 6 to 10 clean, dry 4-ounce bottles. Female patients should use clean, dry, wide mouthed jars.

Paste a blank label on each bottle. Number each bottle consecutively beginning with 1. Write the hour and date of voiding on the label as each bottle is consecutively used.

1 One hour after going to bed at night, empty your bladder *while still in bed*, using a bed pan or bottle, have someone else discard this urine.

2 When you awaken in the morning, *while still in bed*, pass your urine into bottle No. 1.

3 Get out of bed, and kneel on the floor with your head erect and your shoulders thrown back for 10 minutes by the clock. Then, *while still kneeling*, pass your urine at the end of this time into bottle No. 2.

4 Do not drink any liquids (water, coffee, tea, soups, milk and so forth) all day.

5 You may now have your breakfast and go about your daily routine.

6 From now on, whenever you have to pass your urine, do so into one of the labeled bottles or jars, and write the date and hour of voiding on the label.

7 The last urine saved will be that which is passed in the morning.

8 Please bring all the bottles, properly labeled to the clinic (or office) on the morning.

Each sample of urine was tested for albumin by the Heller ring method, as follows: Approximately 2 cc of concentrated nitric acid was poured into a small wineglass, and the urine was filtered so that the filtrate overlies the acid. After an interval of one minute, the line of contact of the urine and acid was carefully observed for the

*From the Nephritic Clinic and Medical Service, Beth Israel Hospital and the Department of Medicine, Harvard Medical School.

†Instructor in medicine, Harvard Medical School; associate visiting physician, Beth Israel Hospital.

presence of a white ring indicating the presence of albumin. A ring seen only against a black background was considered a slightest possible trace (<+); a ring observed against any background was considered a very slight trace (+); a ring seen against any background and just visible from above was considered a slight trace (++); a ring which was opaque from above was considered a trace (+++); and a very flocculent ring opaque from above was considered a large trace (++++).

In the performance of the Heller ring test for albumin, it is important to use clean glassware, good filter paper (Whatman's No. 1) and a good light source. Cloudy and alkaline urines should be centrifuged before they are filtered.

The specific gravity and reaction to litmus of each sample of urine were also determined. The sediment obtained by centrifuging the sample passed in the clinic or office was studied for formed elements.

RESULTS

Constant albuminuria. In 62 patients (Table 1), albumin was present in *all* samples of urine, irrespective of the time of day, activity or position. The lordotic position usually had no effect on the albumin excretion, while the assumption of an upright position usually resulted in an increase in excretion of albumin over that of the recumbent position.

Postural albuminuria. In 40 patients (Table 1), albumin was not found in the morning sample

the end of the ten-minute period of exaggerated lordosis. Albuminuria continued throughout the day until evening.

Type 3. Albumin was not found in the urine voided at the end of recumbency and after lordosis.

TABLE 2. Time of Occurrence of Albuminuria in Ambulatory Patients.

KIND OF ALBUMINURIA	AFTER NOCTURNAL RECUMBENCY	AFTER TEN-MINUTE LORDOSIS	AMBULATORY STATE			
			MORNING	NOON	AFTER NOON	EVENING
None	0	0	0	0	0	0
Constant	+	+	+	+	+	+

Type 2	0	+	+	+	+	0
Type 3	0	0	+	+	0	0
Type 4	0	0	+	+	+	0
Type 5	0	0	0	0	+	+

+ = albumin present, 0 = albumin absent

dosis. It appeared promptly after the upright position was assumed and continued until midday, but was absent in the afternoon and evening.

Type 4. Albumin was not present in the urine voided during recumbency and after lordosis, but appeared in the urine voided after the upright position was assumed; it continued to appear until evening.

Type 5. Albumin was present in the urine only in the afternoon and evening.

Types 2 and 5 of postural albuminuria were most frequently found. The type usually varied

of urine collected in bed. Albuminuria appeared following the assumption of the upright position and activity. The findings in this group (Table 2) fell into five categories:

Type 1. Albumin was not found in the urine collected at the conclusion of the period of recumbency; there was marked albuminuria at the end of a ten-minute period of exaggerated lordosis. Albuminuria disappeared by midday.

Type 2. Albumin was not found in the urine collected at the conclusion of the period of recumbency; there was marked albuminuria at

from time to time in a given patient. Occasionally in a patient with postural albuminuria, albumin was absent from the urine during a given test period, only to recur in subsequent studies.

Occasional albuminuria. In 21 patients (Table 1), albumin was found in the urine occasionally without any relation to recumbency, lordosis, the upright position or activity.

COMMENT

The test. The purpose of the voiding one hour after going to bed was to eliminate the possibility

of including in the morning sample urine formed while the patient was up and about the day before. The conditions of a concentration test were observed during the entire day by the rigid restriction of the intake of fluid so that if the maximum specific gravity was 1.026 or higher in one of the samples, renal function was considered to be normal.

No matter what the etiology of the albuminuria is, the urine voided in the midmorning after the patient has been up and about will show albumin oftener than any other voided during the twenty four hour period (Table 2). This fact must be borne in mind in studies of the incidence of albuminuria.

Constant albuminuria. The finding of albumin in all samples of urine, regardless of the time of day, position or activity, in the 30 patients with overt glomerulonephritis, pyelonephritis and lupus erythematosus is strong evidence that constant albuminuria indicates organic renal disease. In this group are included 7 patients with chronic latent glomerulonephritis who have been followed for five to ten years after the initial attack of the disease. These patients, although symptomless and nonhypertensive, have shown constant albuminuria with normal renal function. If the initial attacks had been insidious instead of overt, one might be at a loss to explain the constant albuminuria.

The finding of constant albuminuria in 21 patients with primary arterial hypertension is further evidence that constant albuminuria indicates some form of chronic disease involving the kidney. In patients with primary arterial hypertension albuminuria may be absent for many years, later it may appear in an occasional urine, to be followed after a period of months or years by constant albuminuria, but never by postural albuminuria.

Of the 11 patients with constant albuminuria with no definitely diagnosable renal disease when first seen, one subsequently developed the manifestations of an acute episode of glomerulonephritis, another developed those of an acute episode of pyelonephritis, and a third developed hypertension after albuminuria had been constant for a long period of time. It is therefore believed that constant incidental albuminuria as above defined, with or without hypertension, indicates organic renal disease.

Postural albuminuria. Six patients recovering from an initial attack of glomerulonephritis or pyelonephritis showed postural albuminuria for several months before the albuminuria completely disappeared. The appearance of postural albuminuria in such patients, therefore, should not be regarded as evidence of persistent renal disease.⁷

Postural albuminuria of one type or another maintained over a period of months or years was

found, however, in patients in whom the history, physical examination and study of the urinary sediment failed to reveal anything suggestive of organic renal disease. None of these patients developed either constant albuminuria or overt renal disease. The finding of persistent postural albuminuria is therefore not to be considered evidence of organic renal disease.

Occasional albuminuria. Occasional albuminuria was found in patients with many conditions.^{8,9} It is significant only in patients with primary arterial hypertension where it may be followed after a period of months or years by constant albuminuria.

CONCLUSIONS

A method of study of albuminuria in ambulatory patients without symptoms is presented. It consists of the study of the concentration of albumin in consecutive samples of urine voided over a period of twenty-eight to thirty-four hours under fixed test conditions.

Such albuminuria may be constant, postural or occasional.

Constant albuminuria is found in all patients with overt chronic nephritis.

Postural albuminuria is present in patients without any evidence of organic renal disease. A small number of patients recovering from an initial attack of overt nephritis show postural albuminuria for several months before the urine becomes free of albumin.

Constant albuminuria even in the absence of any history of an antecedent overt episode and of any other findings is indicative of organic renal disease.

Patients with primary arterial hypertension may show no albuminuria or may show occasional albuminuria or constant albuminuria, but never postural albuminuria.

The urine voided in the midmorning after the patient has been up and about will show albumin more often than any other voided during the twenty four hour period.

MEDICAL PROGRESS

CANCER*

IRA T. NATIANSOHN, M.D.†

BOSTON

STATISTICS of the past decade reveal a decided increase of cancer in the general population. They also demonstrate that the rise will continue at a more rapid rate in the next quarter of a century unless more adequate preventive and specific measures are established. Advances in the prevention and therapy of other diseases are in part indirectly responsible for this rise in the cancer rate, inasmuch as they have significantly prolonged the life expectancy of the individual. It has been shown that the probability of the development of cancer increases steadily with advancing age.¹ It is obvious, therefore, that the cancer problem will become more important since it is the second cause of death in this country even at the present time. Recognition of these facts has led to a recent increase in interest in both the clinical and experimental aspects of the disease. This is evident from the accumulated literature on the subject and the establishment of public-health programs and new institutes and clinics. It has often been said that experiments on cancer in the laboratory animal cannot be applied to the problem in human beings. These statements are only partially true; for evidence will be presented which suggests that utilization of observations in both the human being and the animal is necessary to study more intimately the nature of the disease. There are many analogies in cancer between man and beast.

It is the purpose of this review to present the more practical and interesting aspects of the problem, in the hope, that they may stimulate the physician to a more careful search for preventive, diagnostic and therapeutic procedures, and to inform him of the possibilities of advance in the future.

ETIOLOGIC FACTORS

Precancerous Lesions

Much of the recent work has been centered around precancerous lesions. Recognition of such tissue change is obviously of the greatest importance, since effective treatment would do much to

lessen the incidence of cancer. Precancerous tissue is that which has a greater tendency to develop cancer than other tissue. It has been recognized more and more that neoplastic disease seldom develops in healthy structures. The theory of chronic irritation is compatible with this viewpoint. Distortion of healthy tissue by trauma or by disease appears to be in the same category. Moreover, it is known that atrophic and degenerative changes appear with old age. It was pointed out above that the liability to cancer increases with old age, suggesting that most individuals may develop the disease. Is this a result of changes in cellular metabolism that render the organism susceptible to a potential carcinogenic factor? At any rate, it is apparent that the substrate or soil is a most important factor in determining the effect of an unknown agent in the production of cancer. Factual data suggest that these factors are closely interwoven.

Rhoads² has summarized known precancerous lesions as follows:

Skin

- Keratosis of atrophic skin
- Xeroderma pigmentosa (atrophy)
- Radiation dermatitis (atrophy)
- Burn scars and lupus (atrophy)
- Arsenic dermatitis (atrophy)

- Kraurosis vulvae (atrophy)
- Plummer-Vinson disease (atrophy)
- Thyroid cancer after hypothyroidism
- Cancer in undescended atrophic testicle
- Cancer of liver on cirrhosis
- Leukemia on aplastic anemia

To these may be added suspected and other known precancerous lesions such as those from hormonal and vitamin deficiencies, leukoplakia, chronic gastritis, chronic mastitis, Paget's disease of the breast, luetic glossitis, and changes produced by chemical, thermal, actinic and physical injury that frequently precede or accompany the development of carcinoma.

Pack and Wuester³ in discussing the onset of cancer of the skin point out that this process "is initiated by two factors at work; one an intrinsic change in the structure and function of the skin whereby it loses in some degree its protective capacity against injuries, and the other an extrinsic

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, Vol. III, 1942* (Springfield, Illinois: Charles C Thomas Company, 1942. \$5.00).

factor such as mechanical trauma or physical irritation." It is held that the majority of cancers of the skin and stratified mucous membrane may be "scar" cancer.^{3,4} Many of these lesions on which cancer originated may have been so small as to pass unnoticed, or may be obscured by the cancer itself. Similar changes may precede cancer in other organs that are not available for direct examination.

Diet

At periodic intervals statements have appeared by scientific workers, and quacks as well, that certain diets or elements in the diet are conducive to the formation of cancer. These ideas have been discarded as frequently as they appeared because of lack of confirmatory data. However, in recent years observations have been made in human subjects and laboratory animals that suggest a possible etiologic relation between cancer and diet.

It has been demonstrated that variations of the diet in mice can significantly alter the incidence of several types of spontaneous and induced tumors.^{5,6} Mice that remained healthy on a calorie-restricted diet but containing the essential dietary elements showed a lesser incidence of tumor formation as compared with the controls fed *ad libitum*. Moreover, the addition of fat to the basal ration to render the diet high in calories significantly increased the incidence of certain tumors, whereas others were unaffected.⁷⁻⁹ It may be concluded from these studies that the alteration of the caloric content alone was responsible for the results obtained, although other factors may be involved as a result of the additional fat. The application of these experimental studies to human cancer may prove significant. A review of life-insurance statistics dealing with the relation of body weight to cancer reveals that overweight persons are likelier to develop cancer than those who are average or underweight.¹⁰

However, other factors in the diet may be of importance. One of the most fascinating studies is that of primary cancer of the liver. It has been observed that the disease is common among all pigmented races, in some instances over forty times as frequent as in Whites. The Japanese, the Japanese, African aborigines and the Chinese have the highest incidence. Filipinos and British Indians are also peculiarly susceptible.¹¹ Racial factors may play a prominent role; on the other hand, the radically different dietary and drinking habits of these races may be of equal or greater importance, especially since cirrhosis of the liver is almost always associated with the cancer. It is likely that both factors operate in the production of the disease.

Many attempts have been made to prove the influence of diet on cancer production. Kinosita,¹² using dimethyl-amino-azobenzene, known as butter yellow, was successful in producing liver cancer in rats. It is interesting that, as in human beings, certain strains of rats developed the hepatoma more readily than others. In most cases the cancer was preceded by cirrhosis. The basic diet used was rice, to simulate the food of the natives. It was further found that substitution of wheat bread for rice markedly reduced the incidence of the cancer.¹³ Following these observations much has been done to find other agents that might be effective in the production and inhibition of the disease. For example, feeding of furfural, which is an ingredient of the Japanese rice wine, sake, to rats resulted in liver cirrhosis but no cancer.¹⁴ Edwards¹⁵ fed carbon tetrachloride to mice and produced hepatomas in 100 per cent of the cases.

It is now known that the addition of yeast, rice-bran extract, yeast extract, liver and kidney reduces the incidence of butter-yellow-induced liver cancer. Diets supplemented by riboflavin and casein, or with combinations of the members of the vitamin B complex, alone or in addition to cystine and choline, are also effective in prevention of the hepatoma.¹⁶ Of further interest is the report of du Vigneaud et al.¹⁷ To a diet highly protective against butter-yellow tumors, sufficient egg white (avidin) was added to produce a borderline biotin (vitamin H, which is essential for many forms of plant and animal life) deficiency. One group of rats was fed the diet alone and another group received crystalline biotin in addition. No tumors were found in the biotin-deficient group, whereas hepatomas were found in the animals whose diet was supplemented by biotin. Addition or subtraction of certain of the essential dietary components is also instrumental in increasing or decreasing the incidence of other types of neoplastic disease in animals, such as leukemia and spontaneous breast tumors.^{18,19}

Of interest in respect to other cancer in human beings is the relation of dietary deficiency (particularly of the vitamin B group) to such lesions as papillary atrophy and leukoplakia of the oral cavity.²⁰ There is further evidence that these changes are associated with disorders elsewhere, as is shown by a high incidence of achlorhydria and functional and organic changes in the gastrointestinal tract. Administration of yeast is occasionally followed by a complete or partial remission of the lesions and symptoms.

Physical and Chemical Agents

Physical agents. The importance of changes produced by physical agents as a factor in cancer

formation has been mentioned previously. It has been shown that injury produced by radiation, burns, sepsis or other irritants may predispose to the development of tumor. In this regard the effect of solar radiation or actinic rays in relation to skin carcinoma is of much interest. Statistics reveal that individuals who are exposed to the sun and other elements have a higher incidence of skin cancer than others.²¹ Persons living in southern climates fall within this category. Moreover, skin cancer is more prevalent in exposed parts of the body, such as the face and hands. To test this hypothesis the skin of mice has been exposed to ultraviolet light. Cancers were produced in that part of the skin exposed in a high percentage of cases.²²

Carcinogenic chemicals. To date approximately two hundred and fifty chemical compounds possessing carcinogenic potency have been synthesized.²³ They differ widely in the speed and in the consistency with which they produce cancer in the experimental animal. Dunlap and Warren²⁴ have shown that slight changes in structure are followed by major changes in activity. The relation of the carcinogens to industrial chemicals that produce cancer is well recognized and has been summarized in a previous report.²⁵ These substances are of importance because they provide a tool by which the process of carcinogenesis can be studied. Interest at present is greatest in those chemicals which possess properties similar to those which may possibly be formed in the body. Experiments on the metabolism of one of these carcinogens (1,2,5,6,dibenz-anthracene) have shown that it is excreted as a phenolic derivative in various species of animals.²⁶ This excretion product is non-carcinogenic and is apparently detoxified in the body. Discovery of the mechanism by which this takes place may prove of importance, especially since it may enable one to study the influence of various agents on the production and inhibition of tumors.

Tissue extracts. Attempts have been made to demonstrate a carcinogenic action in cell-free extracts of tissue and excreta from patients with cancer. Tumors have been produced in animals by extracts of liver as well as from the urine of both normal and cancer patients.^{27, 28} These findings must be interpreted with caution, but this mode of approach is an interesting one and may yield significant information in the future.

Tobacco tars. Because of the possible connection between tobacco and the production of cancer of the oral cavity and lung, many investigators have studied the carcinogenic effects of destructive distillates of tobacco and of pipe tar.^{29, 30} The results are variable depending on the method of preparation and testing, but it has been reported

that after painting rabbits' ears with the material, papillomas and in some cases carcinomas developed. Others,³¹ using different animals or different distillates, have reported negative results.

Hormones. Until recently, interest in hormones as etiologic factors in cancer has been focused on the breast and cervix. At the present time, however, new facts may shed further light on the problem. The estrogenic hormones have been shown to be responsible for the production of adenomas of the hypophysis,³² interstitial-cell tumors of the testes,³³ fibromyomas of the uterus³⁴ and carcinomas of the cervix³⁵ in certain strains and species of animals. On the other hand, removal of the ovaries in mice,³⁶ rats and guinea pigs³⁷ of susceptible strains leads to the formation of adrenal hyperplasias and tumors. The possible relation of estrogens to cancer of the breast and of androgens to cancer of the prostate in human beings are of great interest, but as yet there is no good evidence to prove the hypothesis.

OTHER STUDIES

Genetics

The effect of foster nursing on the augmentation or inhibition of spontaneous breast tumors in mice of high and low cancer strains has been referred to in a previous report.²⁵ Prior to this finding it was not possible to produce cancer of the breast in males of low tumor strains by the administration of estrogenic hormone. However, the nursing of these males by mothers with a high cancer incidence, combined with the injection of estrogenic hormone, has resulted in the appearance of a significant number of cancers of the breast.³⁸ Spontaneous pulmonary tumors are unaffected by foster nursing, but there is evidence that the incidence of leukemia in susceptible strains can be altered by this procedure.³⁹ The factor responsible has been found in both the milk and blood of the animals.^{40, 41} Its exact nature is unknown.

Heterologous Transplantation of Human Tumors

Greene⁴² demonstrated several years ago that rabbit cancer could be transferred readily to animals of alien species by utilizing the anterior chamber of the eye as an inoculation site. Since that time he has successfully transferred a considerable number of human sarcomas and carcinomas to guinea pigs and rabbits. The value of such work is obvious, since it not only permits a study of the character of tumor growth, but may also provide information concerning the mechanism of carcinogenesis.

Viruses

This field of cancer is almost entirely confined to animal experimentation. Of interest is the iso-

lation of a specific material from virus induced cottontail-rabbit papillomas. It behaves histologically as the virus responsible for the disease, and has proved to be a nucleoprotein obtainable in solutions of high homogeneity.⁴³ This evidence suggests more than ever the chemical nature of the carcinogenic property of certain viruses. In connection with nucleoproteins it has been suggested⁴⁴ that these compounds are extremely important in determining growth because of their great chemical stability in nongrowing tissue and their high reactivity in growing tissue.

Immunity

So called "immunity" to tumors has claimed the attention of many investigators. Certain tumors in animals regress spontaneously or after transplantation and growth, whereas in other cases, immunity to subsequent growth can be induced by preliminary inoculation of a tumor or by non-specific measures, such as castration and injection of certain hormones.⁴⁵⁻⁴⁶ The Brown-Pearce carcinoma of testicular origin in the rabbit is easily transplantable and thus lends itself readily as a test object. Intracutaneous transplantation of the tumor results in a lesion that grows to a certain size, regresses, and renders the animal immune to subsequent transplants of the same neoplasm except in the anterior chamber of the eye.⁴⁷ In addition, intracutaneous transplantation of the tumor in an animal that already bears the same carcinoma and in which it is metastatic throughout the organs causes regression of all the lesions except those in the anterior chamber. Evidence accumulates that the inhibition is due to complement fixing antibodies developed in the animal and present in the blood serum.⁴⁸⁻⁴⁹ The ability of lesions in the anterior chamber to withstand such an antibody is apparently due to the barrier that exists between the blood and the aqueous humor. Similar possibilities in human tumors must be considered.

CLINICAL FACTORS

One hears the statement that little more can be expected of our present day methods of treatment of cancer. This is true if one does not take advantage of the knowledge gained in the recognition and behavior of the disease. Advances in other branches of medicine have, in an indirect fashion, contributed significantly to the problem. Cognizance of the facts and intelligent use of such information should enable one to utilize the methods at one's disposal with a greater prospect of cure. This is evident from the great strides that have been made in the treatment of cancers of certain organs that were formerly considered incurable.

Advances in anesthesia and an increasing knowledge of the physiology of the contents of the chest now enable the surgeon to enter the thoracic cavity with as much confidence and ease as when he enters the abdominal cavity.

Carcinoma of the pharynx and esophagus Woolley⁵⁰ has reported on the successful removal of the hypopharynx and upper esophagus for carcinoma in 4 subjects, with excellent functional and cosmetic results. This operation was devised primarily to eradicate lesions that were not amenable to radiation therapy. Two of the patients were free of the disease at the time of the report, and the others had died of persistent or metastatic disease.

Carcinoma of the esophagus has taken a heavy toll, and until recently it has been considered a hopeless disease. Few cures have been reported by either radiation or surgery. Esophageal cancers are usually of the squamous-cell type, which should respond well to radiation. However, the organ is hollow and thin walled so that perforation into the mediastinum even after regression of the lesion is of common occurrence. Surgical extirpation has been frequently attempted, but until recently it was successful in only a few cases. Churchill⁵¹ has summarized the surgical aspect of the problem in a recent report. Advances in diagnostic, physiological and technical knowledge have made possible the successful removal of suitable lesions in a fair number of cases. Garlock⁵² states from his own experience as well as that of others that the average patient with a carcinoma of the middle third of the esophagus stands a 54 per-cent chance of surviving the operation and a 30 per-cent chance of living more than one year. With lesions of the lower third there is approximately a 70 per-cent chance of surviving the operation and 100 per-cent probability of living more than two years. These figures refer only to operable cases, and failures in the group are frequently due to lymph node involvement.

Carcinoma of the lung. This condition is definitely increasing and at present ranks among the highest of causes of death from cancer. The reason for this is not clear, but it is believed that tobacco-smoking, tarred roads, fumes from combustible fluids or the influenza epidemic of 1918 may be contributory. It has been stated by several observers that the problem of cancer of the lung is not very different from that of cancer of the stomach. In fact, the resectability rates and the cures after successful surgical procedures are almost the same. The main difference is the higher mortality rate in surgery of the lung.⁵³⁻⁵⁵ The five year survivals in both groups are still considerably below those of most types of cancer. Metastasis to the regional lymph nodes and to re-

more sites in addition to local extension renders many cases incurable. This is due in part to the fact that the disease is seldom diagnosed in its early stages. It is reasonable to assume that, when the local process is technically operable, metastasis or extension has not taken place. It has been pointed out that all patients having primary cancer of the lung without evidence of local extension or distant metastasis should have an exploratory thoracotomy to determine operability. This may be aided preoperatively by artificial pneumothorax. These measures are especially valuable since x-ray examination alone frequently gives an erroneous impression of the size and extent of the tumor.⁵⁶

Because radiation therapy has been disappointing, more frequent attempts at surgical removal have been made and are increasingly successful. The ideal operation, which consists of total removal of the primary growth and block dissection of the regional lymph nodes as in carcinoma of the stomach, breast and so forth, is not technically feasible. It is the consensus that total pneumonectomy, which may permit removal of the primary lymph nodes, is the procedure of choice in spite of the high operative mortality. Lobectomy may be used for a limited group with peripheral tumors and without gross involvement of the regional lymphatics. This is surgically and anatomically a poorer procedure than total removal of the lung.

Carcinoma of the stomach. Like cancer of the lung, there is an extremely high incidence of this disease. The introduction of improved and new methods, particularly that of gastroscopy, has considerably improved diagnoses, thus increasing the number of cases suitable for radical curative procedures. Of particular importance is the problem of the gastric ulcer. In general there has been a lack of understanding of the possibility that many of these lesions are malignant. As Gray⁵⁴ has pointed out, "It is not really so important to quibble as to whether or not a particular lesion was once a benign ulcer as to attempt to determine immediately whether or not the lesion under consideration is malignant." Mallory⁵⁷ has demonstrated that peptic ulceration of carcinomatous tissue in the stomach is not uncommon. It is assumed that it occurs in the early stages when secretion is fairly normal. This suggests that certain ulcers of the stomach are cancer to begin with and may in the early stages fall into the category of lesions known as cancer in situ.

Because of the difficulty in the differential diagnosis between gastric ulcer and cancer, the recent contribution of Allen and Welch⁵⁸ is of significance. From a statistical analysis of 277 cases in which the original diagnosis was gastric ulcer, 39 cases (14 per cent) finally proved to have cancer,

whereas 17 patients (6 per cent) with a preoperative diagnosis of cancer proved to have a benign ulcer. The approximate incidence of cancer in ulcers at various sites in the stomach has been stated by them to be as follows: greater curvature 100 per cent, prepyloric area 65 per cent, anterior and posterior wall 20 per cent, pyloric valve 10 per cent and lesser curvature 10 per cent. On the basis of these studies, Allen and Welch have made the following recommendations, which will bear repetition. Immediate surgery is recommended for any one of the following reasons: the ulcer is of short duration and the patient is over fifty years of age; the ulcer is over 2.5 cm. in diameter; there is no free hydrochloric acid in the stomach; the ulcer is in the greater curvature or in the prepyloric region; it is chronic and on the lesser curvature. Hospital observation and treatment for one month is recommended if the ulcer is acute and in a young patient, is under 1 cm. in diameter, or is on the lesser curvature or the anterior or posterior wall. If healing is complete in one month, the patient should be studied one month after discharge from the hospital. If healing is not complete in one month by roentgenologic or gastroscopic examination, then surgery is advisable. Allen and Welch conclude therefore that gastric ulcer is fundamentally a surgical lesion, that it cannot be distinguished from cancer in a high percentage of cases, and that gastric cancers which simulate gastric ulcers are an especially favorable group for cure. The end results of gastric resection from ulcer seem to substantiate this same form of treatment even if the ulcer is proved to be benign. These opinions are agreed with by most surgeons who have had an extensive experience with such lesions.

Increased knowledge of the mode of spread of carcinoma of the stomach, coupled with physiological advance and improvement in surgical technique, has widened the scope of treatment of the disease, especially as regards cases suitable for operative removal. Subtotal gastrectomy definitely limits the number of cases that can be cured. Removal of the omentum increases the possibility for cure, since it includes additional lymph nodes which may be invaded by the disease. Of late there have been an increasing number of successful total gastrectomies for lesions which were previously considered inoperable because of their extent and location. This applies particularly to lesions of the cardiac end of the stomach.⁵⁹ With the increasing incidence of successful resections for carcinoma of the lower third of the esophagus, interest has been renewed in lesions of the cardia.

Garlock⁶⁰ stresses that the biopsy report is of great value in determining the approach to lesions in the region of the cardia and lower third of the

esophagus. If the lesion is of the squamous-cell type it is probably of esophageal origin, whereas adenocarcinoma suggests an origin in the cardia of the stomach. These tumors are definitely different in respect to their mode of spread, and therefore a different surgical approach is indicated. Garlock states that on the basis of combined experience of various authors the patient with a resectable cancer of the upper end of the stomach has a 60 per-cent chance of surviving the operation and an 80 per-cent probability of living more than two years.

MISCELLANEOUS TOPICS

Hormones

The accumulation of information concerning the action of various hormones on specific organs, especially as regards their stimulating and inhibiting properties, has called attention to their possible significance as etiologic or therapeutic factors in neoplastic disease. Furthermore, studies of excretion rates of the sex hormones in the urine have provided valuable leads with specific types of tumors.

The most striking relation of hormones to a carcinoma of an organ normally acted on by the sex hormones has been provided by Huggins⁶¹ and his colleagues in carcinoma of the prostate. This has been the subject of a recent report by Quimby.⁶² It is well known that osseous metastases from cancer of the breast frequently regress in a most dramatic fashion following castration by either surgery or radiation. This has resulted in diminution of pain and in younger persons has slightly increased the life expectancy, but has had no effect on the subsequent course of the disease. By contrast, the results following orchidectomy for cancer of the prostate are much more encouraging, although it is too early to forecast what can be eventually expected from the procedure.

Recently Farrow and Adair⁶³ reported on the effect of orchidectomy in a man of seventy-two with cancer of the breast. There was complete relief from bone pain and evidence of increased calcification and healing of the metastatic bony deposits. The primary lesion, which had no treatment, also seemed to decrease in size.

Injection of hormones in an attempt to inhibit the progress of breast cancer has also been attempted.⁶⁴ The administration of either estrogens or androgens as measured by clinical, laboratory and radiologic findings caused an increased bone absorption, an elevation of serum and urinary calcium and increased activity in bone metastases. This did not occur in persons without skeletal dis-

ease. This is of extreme interest when compared with cancer of the prostate and its metastases, since estrogens in these lesions appear in some cases to augment the effect of orchidectomy, whereas androgens have proved deleterious.

Excretion of Sex Hormones

Carcinoma in general The findings of several investigators who have studied the urinary excretions of the sex hormones in patients with carcinoma of all types may be summarized as follows:

Gonadotropic hormones (pituitary origin) — There is no consistent pattern of excretion. Variations from normal may be correlated more closely with the physiologic state of the individual than with the presence of a carcinoma.

Estrogens (female sex hormones) — Pincus and Pearlman⁶⁵ report from their studies on pooled specimens of urine that the estrogen excretion in women with cancer is lower than that of normal women. In men this incidence was reversed and was thought to be due to a specific increase in one type of estrogen (estriol).

Androgens (male sex hormones). — With few exceptions most studies of the androgens have been confined to the excretion rates of the 17 ketosteroids, which probably represent not only the biologically active androgens, but also closely related catabolic products of these and similar compounds that are not active in their excreted form. Pearlman,⁶⁶ Dobriner⁶⁷ and Nathanson⁶⁸ all agree that as compared with normal persons, patients with cancer have a lowered excretion of these compounds. Recent studies by Dobriner⁶⁷ and Pincus⁶⁹ further indicate that these compounds are not excreted in a normal relation with one another. There is evidence that several of the substances that are excreted by normal persons are absent from the urine of cancer patients. Several other compounds not previously identified have been found in the urine of those with neoplastic disease.

Specific lesions Carcinoma of the breast — Ross and Dorfman⁷⁰ could find no variation from normal in the estrogen and androgen excretion of women with cancer of the breast. Taylor⁷¹ and Nathanson⁷² found lowered estrogen and 17 ketosteroid secretion rates in similar patients as compared with normal women of the same age group. The differences were not considered as significantly altered from normal, since abnormal physiologic states due to other factors may have been responsible. Yolton and Rea⁷³ studied these excretions in 2 men with cancer of the breast, but found no difference from others of the same age. It can be concluded from these studies that the excretion levels of the sex hormones give no true index of

these agents in cancer of the breast. They do indicate, however, that the cancer may be initiated and maintained in the presence of normal hormonal levels.

Carcinoma of the prostate.—Scott and Vermeulen⁷⁴ found that before castration the level of 17-ketosteroid excretion in patients with cancer of the prostate was well below that of normal males of a younger age, but very close to levels for normal men of the same age and castrates. Castration leads first to a fall in 17-ketosteroids, followed by a rise. Estrogen excretion is low and decreases still further after castration. Castration leads to a moderate rise in urinary gonadotropins, which is slight compared to the values reported for younger castrates.

Testicular tumors.—It was formerly thought that the levels of the urinary excretion of anterior-pituitary-like hormone found in patients with testicular tumors paralleled the rapidity of growth and the grade of malignancy. Evidence by Twombly⁷⁵ indicates that there is no direct correlation between the excretion rate and the type of tumor. There is a suggestion of correlation with the prognosis of the disease. Cases that excrete 10,000 mouse units or over more than once are invariably fatal.

Functioning tumors.—Excretion levels of the sex hormones may be of distinct value in the diagnosis of functioning tumors of endocrine origin.⁷⁶ For example, differentiation of three types of tumors in females that produce similar syndromes may be aided by these studies. Patients with pituitary basophilism may excrete increased or decreased amounts of gonadotropins; the estrogens may be normal or lowered and the 17-ketosteroids within normal limits.^{68, 77-79} In adrenal hyperplasia the gonadotropic hormones are usually normal, the estrogens normal or elevated, and the 17-ketosteroids moderately elevated.^{68, 77, 78} As regards the 17-ketosteroids there is usually a normal relation between the various components.⁷⁷ It is believed that the 17-ketosteroids arise from both the adrenal glands and the gonads. There are two main groups: the alpha, which are probably of both adrenal and gonadal origin, and the beta, of adrenal origin only. They are usually excreted in a definite relation, that is, alpha 85-95 per cent, beta 5-15 per cent. In adrenocortical carcinoma the estrogens may be significantly elevated, but the most striking finding is a marked increase in the 17-ketosteroid excretion.^{68, 77, 78, 80} Moreover, there is a distinct shift in the relation between the components,^{67, 77} that is, a marked increase in the beta fraction, which may exceed 50 per cent of the total excretion. This is of the utmost importance in the differentiation of benign hyperplasia from cancer of the adrenal cortex. Men with pituitary basophilism

and boys with adrenal tumors exhibit the same excretion rates as the females. In men with adrenal tumors, feminization usually occurs, and this is reflected in a marked increase in the excretion of estrogens and normal or slightly elevated 17-ketosteroids. Arrhenoblastoma of the ovary gives variable results. Generally the estrogens are lowered and the 17-ketosteroids are normal or slightly elevated.^{68, 78} Granulosa-cell tumors of the ovary usually result in the excretion of large quantities of estrogenic hormone, but this is not necessarily true in all cases.⁶⁹ As more cases are studied these preliminary findings are certain to be clarified, and may prove of significance in the study of neoplastic disease.

METHODS OF THERAPY

Chemosurgery

Mohs⁸¹ has developed a new technic for the treatment of certain neoplasms, which he terms "chemosurgery." The idea originated from the well-known use of and occasional cure from caustics and fixatives employed by cancer quacks. This method involves chemical fixation of tissue with any of a number of agents. Briefly the method is as follows: The fixative is applied to the surface of the tumor, the dose depending on the penetration desired. Twenty-four hours later the fixed tissue is excised surgically; this can be done with a minimum of bleeding. The removed tissue is sectioned, and the location of cancerous areas is determined. Thereafter there is a daily repetition of the process, but only the neoplastic areas are treated until a microscopically noncancerous plane is reached. Mohs states that the main advantage of the technic is that it enables extirpation of an accessible neoplasm with unprecedented reliability, since it includes all unsuspected extensions and produces a minimal destruction of tissue. The method requires special training and painstaking control. Mohs reports a large series of patients with cancer of the skin, lip and so forth who have been free of disease for one to four years, but makes no claims as to its greater efficacy as compared with other methods in effecting a permanent cure.

Refrigeration

It is now generally agreed that refrigeration is of no particular value in the treatment of cancer, except in so far as it may produce a diminution of pain. The difficulties of the method, the complications and dangers of its use such as pneumonia and cardiac failure and the efficiency of other measures for the treatment of the lesion and relief of pain relegate this type of treatment to a few selected cases where it may be worth a trial.

Radiation Therapy

The use of x-rays, radium and radioactive isotopes in the therapy of cancer has been reviewed by others.^{82, 83} in this series. It may be added that Donovan and Warren⁸⁴ have shown that the intracavitary use of radium in cancer of the endometrium is seldom effective in completely eradicating the disease. In the past few years, the use of intracavitary x-rays by means of special cones has been a most valuable adjunct in the treatment of cancers of the oral cavity, bladder and cervix, when combined with the usual methods of external radiation.

Treatment of Pain

Advances in neurosurgery have helped considerably in combating the pain from cancer. There have been many reports regarding effective procedures. Grant⁸⁵ has summarized and presented data on what can be done for the relief of pain by interruption of the sensory pathways, discussing the hazards involved and the justification for the procedures. Decisions must rest on the site and rate of growth of the tumor, the life expectancy, the degree and location of pain, the general condition of the patient as an operative risk and the amount of sedation or opiate necessary for relief. Grant discusses the indications for and results of such procedures as subarachnoid injection, nerve section, chordotomy and rhizotomy. Results from these measures are most encouraging. Munro⁸⁶ is of the opinion that the development of pain in cancer of the head and neck is associated with the effect of x-ray therapy. He advocates surgical denervation of the cancer-bearing areas in selected cases as the first step in the treatment of the disease, to provide against possible subsequent pain and as an aid to more efficient therapy. Reports on the use of cobra venom are variable, but it seems to be worth a trial in selected cases. All authors rightly deplore the indiscriminate use of morphine in cases of terminal cancer, especially because of the fact that the symptoms due to addiction far outweigh the pain produced by the disease.

METASTASES

An increase in the number of cases in which the primary cancer has been controlled has resulted in concentrated studies on the modes and sites of metastases from various organs. This is necessary since therapy must now be directed more rigorously toward these secondary deposits in an effort to effect a complete cure of the disease. Willis⁸⁷ has supplemented his original classical monograph on the spread of tumors and points out the more likely routes and location of the disseminated tumor. Other investigators have been primarily

concerned with lymph-node metastases which are amenable to treatment. Of particular interest is the utilization of the Spalteholz clearing method by Gilchrist and David⁸⁸ and Collier et al.^{89, 90} to study the incidence and sites of metastatic nodes from various lesions of the stomach, colon and rectum. It has been demonstrated that the number and extent of nodes involved are far greater than was formerly realized. Duffy⁹¹ and Martin⁹² have confined their work to lesions of the oral cavity. A comprehensive study of the problem based on an analysis of almost 6000 cases has been made by Taylor and Nathanson.⁹³ On the basis of their findings, combined with the experience of others, they have set down criteria for diagnosis and methods of management of the common and many of the rarer types of tumors.

CANCER CONTROL AND PUBLIC-HEALTH PROGRAMS

The Massachusetts Department of Public Health continues its program of education. Teaching clinics are held frequently at various centers throughout the state. This program has been of inestimable value, since it has resulted in earlier and better diagnosis, improved treatment and a decrease in the delay before treatment is instituted. Even though the cancer rate has increased, the morbidity and mortality from the disease have shown a relative decline. The American Society for the Control of Cancer is now aided by the Women's Field Army in its campaign. The latter organization has been effective in raising money to provide more efficient facilities for the care of the patient and for education. Many other states, as well as the federal government, have adopted progressive programs. In addition, new institutes and hospitals have been opened. Notable among these are the National Cancer Institute at Bethesda, Maryland, where research in cancer is carried out, the new state hospital in Missouri and a proposed hospital in Texas.

In order to care for persons in the western part of Massachusetts and to relieve the burden on the Pondville Hospital, the Commonwealth has built a 50-bed addition for cancer patients at the state tuberculosis sanatorium at Westfield. One of the pioneer institutions, the Collis P. Huntington Memorial Hospital, has closed its doors because it was thought that it could serve the community more effectively if it were a part of a large general institution. Its functions, including its clinical and research facilities, have been transferred to the Massachusetts General Hospital.

Periodic Examination

There has been much interest in periodic examinations of persons who are in the cancer age. The

efficacy of this program is apparent from the report of MacFarlane,⁹⁴ who has made semiannual pelvic examinations in 1000 women over the age of thirty. In the past three years, 4 early unsuspected cases of cancer of the cervix and fundus of the uterus and 119 lesions of the cervix that were believed to predispose to the development of cancer were found and treated.

* * *

This review of some of the more pertinent material on cancer for the past few years has aimed to give the physician a broad view of the problem as a whole. The details of each type of approach may be learned by consulting the references. It should be realized that much is known of the etiology, diagnosis and treatment of cancer, and it is hoped that the pessimistic attitude so often held will be reversed. The future is promising, but even at present we have at our disposal potent weapons which, if used intelligently and judiciously, will do much to combat effectively a major disease of our aging population.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28481

PRESENTATION OF CASE

First admission. A seventeen-year-old Italian-American girl was admitted to the hospital because of headaches for four weeks.

She was in good health until one evening five weeks before entry, when she went for an hour's ride in an automobile. In the course of the ride the right side of her face was exposed constantly to a cold wind. She also struck the right side of her head against the top of the car, but only hard enough to cause momentary discomfort. Later in the evening there was some twitching of the right side of the face. The next morning, her mouth was "crooked," and she was unable to blink her right eye. She was seen in the Emergency Ward, where she seemed quite weak, and twice tended to faint; she did not, however, lose consciousness.

Examination showed partial paralysis of the entire right side of the face. There were no sensory changes, but slight tenderness was noted in the region of the right facial canal. She was given 75 mg. of thiamine chloride by intravenous injection, and rest was recommended. Eight days later, she returned to the Out Patient Department, complaining of an ache in the right ear induced by loud noises. The facial paralysis was unchanged, and there was, in addition, slight hypalgesia over the right side of the face. A roentgenogram of the skull showed normal convolutional markings and normal configuration of the sella. The left acoustic meatus appeared slightly larger than the right. Five days later, the patient was given massage and electrical physiotherapy for her persistent facial palsy. At about this time she began to complain of "occasional" right frontoparietal headaches, which were sometimes "knifelike" and sometimes "pulling." Twenty-four days after the patient was first seen, facial muscular function was found essentially normal and an audiogram showed bilateral normal hearing. In the next two weeks, the patient experienced headaches of increasing severity. She felt "peppless," easily fatigued and

without appetite. The night before entry, she had some "difficulty in breathing."

The family history was not of interest. The patient had been seen in the Out Patient Department when thirteen years old for a suspicion of rheumatic fever, but this diagnosis had been rejected. At fifteen years she had again consulted the clinic because of increase in size of her right breast, with slight pain, unrelated to the menses; some hypertrophy of breast ducts had been observed.

Examination disclosed an apparently healthy girl. The right breast was slightly larger than the left. A few lymph nodes were palpable in the neck. The heart, lungs and abdomen were not remarkable.

The blood pressure was 130 systolic, 80 diastolic. The temperature was 100°F., the pulse 100, and the respirations 20.

On neurologic examination, the pupils were equal, but reacted with hippus. The fundi were normal. The visual fields and blind spots had normal configuration. Tests of smell, hearing and taste were negative. There was slight hyperesthesia over the right temporoparietal area, but no other sensory disturbance. The reflexes were physiologic. A slight residual peripheral right seventh-nerve paresis remained. A lumbar puncture gave clear colorless fluid under an initial pressure of 140 mm. of water. The total protein was 25 mg. per 100 cc.; the gold-sol curve was 0011100000, and the Wassermann reaction was negative. An electroencephalogram was negative.

The examination of the blood, including a Hinton test, was negative. The urine also was not remarkable.

During the stay in the hospital the patient's temperature varied irregularly from 98 to 100°F. On the eighth day a slight swelling was noted in the right temporoparietal region. On the tenth day the patient complained of numbness over the right side of her face. The next day she was discharged.

Second admission (nine and a half weeks later). Following discharge the patient was followed for the next five weeks in the Out Patient Department. Her headaches continued as before. Because of a slight increase in the temporoparietal swelling and persistent tenderness in this area, another roentgenogram of the skull was taken. This showed a sharply outlined defect in the right frontal bone, just anterior to the coronal suture, measuring 3 by 2 cm. (Fig. 1). Except for this palpable, slightly tender defect, physical examination was as noted on the first admission.

The temperature was 98.6°F., the pulse 80, and the respirations 20.

The blood and urine were again essentially negative. The blood cholesterol was 134 mg., the calcium 11.7 mg., the phosphorus 2.9 mg., and the phosphatase 1.7 Bodansky units per 100 cc. Roentgenograms of the chest and of the renal tract (pyelograms) were negative. Another roentgenogram of the skull, taken six and a half weeks after the previous one, showed slight increase in size of the bony defect. The outer table of the skull

there was only a mild residuum at the time of admission.

Slight swelling in the right temporoparietal region developed, which was noted to be tender at the time of the second admission (nine and a half weeks after the first admission).

Roentgenograms of the skull seven weeks after the onset of symptoms showed a large, punched-out defect involving the right frontal bone—this despite the fact that roentgenograms of the skull nine weeks before had shown no evidence

FIGURE 1.

was involved to a much greater extent than the inner. On the fifth hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM T. GREEN*: The five most pertinent factors in the history may be listed as follows:

A seventeen-year-old girl was admitted with a primary complaint of right frontoparietal headache of three weeks' duration.

A facial paralysis on the right occurred suddenly one or two weeks before the onset of the primary complaint and improved so rapidly that

of this lesion and, in fact, were interpreted as normal except for a questionable narrowing of the right internal auditory meatus.

The patient was apparently healthy except for the specific complaints that have been mentioned. The first examination confirms this impression. Neurologic findings were entirely within normal limits except for the facial weakness, indicating a lesion of the right seventh nerve. All recorded laboratory determinations gave normal findings.

We are primarily concerned in this diagnosis with the disease as represented by the destructive lesion in the skull. All other considerations are subservient to this one problem.

Let us consider the facial palsy. The question arises whether the facial paralysis is a part of the

*Assistant professor of orthopedic surgery, Harvard Medical School, visiting surgeon, Children's Hospital, Boston

general picture, or an incidental feature. Is the paralysis caused by the lesion that produced the area of destruction in the skull? Is the paralysis central or peripheral in origin?

The facial paralysis came on two weeks before the onset of the headache and five weeks before admission. It involved both the upper and lower portions of the face. It was right sided in distribution (the lesion in the skull was on the right side). This facial weakness came on suddenly with a history of an antecedent "bump" in the area, and on the night before it was noted the patient had ridden in an open car, her face on the involved side having been exposed constantly to a cold wind. I should assume that a tentative diagnosis of Bell's palsy of the ordinary type was made when she was first seen in the Out Patient Department. This paralysis improved rapidly so that a note was made three weeks after its onset that the weakness of the muscle had largely disappeared, although on admission to the hospital it is commented that some residual weakness remained.

In the course of this facial paralysis and before admission the patient complained of a hyperacuity in hearing with pain on noisy stimuli, which might suggest to an orthopedist—who knows nothing about it—that the nerve to the stapedius muscle was involved. One could state that the lesion was infranuclear, not supranuclear, in origin, since the upper facial distribution was involved just as much as the lower face. In supranuclear lesions, this is not true.

The second question, granting that the lesion is infranuclear, is whether the lesion arose before the entrance of the facial nerve into the facial canal, or within the facial canal. If the lesion were in the cerebellopontine angle, one would expect to have involvement of other cranial nerves, including probably the eighth and sixth nerves. There was no evidence of this. In fact, the neurologic findings were entirely negative at all times except for the facial palsy. It is not stated that definite observations were made regarding taste when the facial palsy was marked, although later there was no disturbance in this sensation. All evidence, including the hyperacuity of hearing and the painful hearing on noisy stimuli, indicates that the lesion was peripheral or in the facial canal. Everything suggests that it was an ordinary Bell's palsy, particularly since the lesion improved at quite a rapid rate, but there is one other possibility to be considered as an etiologic factor, which we will discuss later.

Roentgenograms of the petrous portion of the bone were reported as essentially negative, although there is some question whether the internal auditory meatus on the right side was not smaller

than that on the left. I judge that there was no strong feeling about it. I hope that Dr. Holmes will comment on these findings later.

The headache, I believe, was related directly to the lesion that was later demonstrated to be present in the skull, since the site of the discomfort coincided with the position of the lesion. However, on the first admission, the headache could not be explained and the lesion had not been demonstrated. The only significant finding was that, on the patient's eighth day in the hospital, there was a suggestion that she had some swelling in the right temporoparietal region, but it apparently did not cause particular concern and she was discharged.

On the second admission, nine and a half weeks later, the physical findings were essentially the same except that there was more swelling in the temporal area and roentgenograms showed a definite defect. Perhaps we could have the roentgenograms presented at this time.

DR. GEORGE W. HOLMES: I should be inclined to agree with Dr. Green, that the first x-ray interpretation was an attempt to find something,—an attempt to call attention to a possible variation,—but the examiner was not very certain about it. The second time there was a very definite lesion that was not present the first time. It is a sharply defined area of destruction of bone, which occupies a considerable area.

DR. GREEN: I wondered about the relative density and aeration of the mastoid process on each side. How do you account for the difference on the two sides? On one side, there is moderate aeration, and on the other there is increased density.

DR. HOLMES: The patient could have had infection on the denser side.

DR. GREEN: An old sclerosing process?

DR. HOLMES: Yes.

DR. GREEN: But there is no evidence that such infection existed. I imagine that the interest in this patient increased a great deal when the roentgenograms revealed the area of destruction in the skull on readmission. Probably the question was whether the facial palsy arose from the lesion in the skull, but I have pointed out previously that the facial palsy was not supranuclear in origin and, as a matter of fact, if the lesion was a factor in the facial palsy the paralysis would have been on the opposite side, namely, the left.

At the second admission, the patient had a destructive lesion of the skull associated with headache, but there was little general illness. The term "pain" was never used in a description of her complaints. Roentgenograms of the chest were interpreted as normal; there was no evidence of met-

astatic lesions. I assume that there were no other bone lesions, although there is no note that roentgenograms of the remainder of the skeleton were made. Were they taken?

DR. TRACY B. MALLORY: They were taken and were negative.

DR. GREEN: In analyzing the lesion in the skull, certain comments should be made. One always thinks of infection when there is destruction of bone. From the roentgenographic appearance, it is possible that this lesion might have arisen from infection. It is not likely, however. Clinically there was no evidence of it. There were no particular febrile episodes. Tenderness was minimal, and there was no reaction over the lesion. In roentgen appearance it is too clean-cut and smooth and does not show enough reaction in the surrounding bone to be compatible with ordinary pyogenic infection. So far as other types of infection are concerned, one might mention syphilis, but we are not concerned with it as a possibility. In fact, I do not believe that the lesion was due to infection.

Was it a tumor? Various possibilities must be considered, but I think that we can cut short our discussion of these in deference to time. I should say that the destructive area gave little evidence of actual tumor. It must have been quite flat since, when it was talked about after it was noted, it was commented on as a defect. Most tumors of ordinary type grow in a centrifugal concentric fashion, and according to the outline as seen in the skull, if the lesion were a tumor growing in such fashion, there would have been a considerable mass.

I shall not comment on the various types of tumors that this lesion might represent, except to say that I do not believe it is tumor, either primary or secondary.

I might make some comment about the possibility of multiple myeloma. Ordinarily a lesion of multiple myeloma is likely to be smaller than this, but even larger lesions occasionally occur. The patient's age, however, is important. She was seventeen years old, and although multiple myeloma is described in even younger persons, these alleged cases with which I am familiar are open to question.

We then arrive by elimination at the particular disease that I believe this patient had, namely, Hand-Schüller-Christian disease¹—xanthomatosis is a synonymous term. The typical Hand-Schüller-Christian syndrome has come to be associated with multiple destructive lesions of the skull, particularly those which are geographic in type and sharply punched out, exophthalmos and diabetes

insipidus. We know, however, that the latter two features of the syndrome are really due to the location of the lesions in the skull. The diabetes insipidus depends on a lesion involving the region of the sella turcica and the base of the third ventricle; and the exophthalmos is dependent on a lesion that involves the orbital plate. The fact that this patient had neither diabetes insipidus nor exophthalmos does not affect my decision regarding this particular patient.

A couple of years ago, two articles came out within a short time of each other—one "Eosinophilic Granuloma of Bone," by Lichtenstein and Jaffe,² and the second "Solitary Granuloma of Bone," by Otani and Ehrlich.³ Both these articles describe the same type of granulomatous process. I will not comment on the process further except to say that it is characterized by the presence of a large number of eosinophils and large monocytes that show inclusions. During the last twelve years, I have followed quite a few patients with lesions of the type that they described. Dr. Sidney Farber and I⁴ have reported 10 of these, and in all we have seen 16. I shall leave it to Dr. Mallory to discuss the pathologic picture in this type of disease.

DR. MALLORY: Go right ahead.

DR. GREEN: The lesions that we have seen were single in certain patients and multiple in others. In the 10 patients reported, there were single lesions in 4 and multiple lesions in 6. The lesions of the bone were more frequently seen in the skull and in the ribs. The vertebral column and pelvis were involved quite frequently, as well as the long bones. The patients showed a relatively benign clinical course. However, we have seen other patients with similar bone lesions histologically and roentgenographically who also had visceral manifestations; the prognosis in such a case is not good. In the latter group, all patients had visceral manifestations as well as bone lesions at the time we first saw them. The condition in this group may be classified as Letterer-Siwe disease.⁵ Dr. Farber believes that Hand-Schüller-Christian disease and eosinophilic granuloma represent the same fundamental type of pathologic process and, in fact, that Letterer-Siwe disease—that is, the type with visceral involvement—is likewise related.

The patients with eosinophilic granulomas have shown a good response to x-radiation, but I suggest that it should be given in relatively small doses to the particular lesions and the effect should be carefully observed. One is tempted to give heavy doses, but in our experience this is not necessary and it is better to hold something in reserve, since

many new lesions may appear in the course of the disease. Certain of the lesions have healed spontaneously.

The cause of the disease is unknown; in fact the reason that our cases were not published sooner was that we were attempting to determine the etiologic factor responsible for the condition. It has been suggested that the disease might be due to a virus, but there is no proof at this time of such a causative agent.

In connection with the facial palsy, it is entirely possible that a very small lesion in the petrous portion of the temporal bone, which could not be seen in the roentgenograms, might have been responsible, since this bone is frequently involved by the process.

DR. MALLORY: Which of the multiple names do you choose to call it?

DR. GREEN: I do not know what we should call it, but we must call it something to know what we are talking about. We should know more about the etiology of the pathologic process in order to give it a suitable name. At the present time, we give the diagnosis: Hand-Schüller-Christian disease, eosinophilic-granuloma variant.

CLINICAL DIAGNOSIS

Lymphoma?

Metastatic malignancy?

Hand-Schüller-Christian disease?

DR. GREEN'S DIAGNOSIS

Hand-Schüller-Christian disease, eosinophilic-granuloma variant.

ANATOMICAL DIAGNOSIS

Granuloma of bone (Hand-Schüller-Christian type).

PATHOLOGICAL DISCUSSION

DR. MALLORY: The biopsy of this lesion showed a granulomatous process containing foam cells but no eosinophils. Histologically it was very typical of Hand-Schüller-Christian disease. I am entirely in agreement with Dr. Green and Dr. Farber in believing that all these conditions represent transitional forms of a single disease entity without known etiology. Usually the more typical xanthomatous processes are seen in the younger age groups, whereas the so-called "eosinophilic granulomas" are seen in young and middle-aged adults. However, I have seen a marked eosinophilic reaction without cholesterol deposits in a child of three, and marked xanthomatous reaction without eosinophils in a woman in her late forties. This patient was treated by x-ray, and the lesion partly filled in, although it never completely

disappeared. This film shows the situation two years later. She has been clinically free from symptoms.

DR. GREEN: The younger persons, of course, have an advantage in healing. The skull lesions in our patients showed complete healing. This girl was older, seventeen, and this might well account for the residual defect.

DR. FULLER ALBRIGHT: They removed the sum and substance.

DR. GREEN: That might well be a factor, but the substance was removed before the biopsy, if you can judge from the appearance of the film.

DR. MALLORY: Would you be enthusiastic about further treatment?

DR. GREEN: No; it is worth while stating that we have seen multiple lesions representing the various phases of the disease as we interpret them.

DR. JOSEPH C. AUB: Is it not unusual for it to develop so rapidly?

DR. GREEN: No; I have seen a skull treated in one area, and a month later a big new defect in an untreated area.

CASE 28482

PRESENTATION OF CASE

A fifty-two-year-old businessman was transferred to the hospital for study of a disorder that began with a generalized feeling of weakness.

Approximately one and a half weeks prior to admission he contracted an upper respiratory infection, which seemed different from the usual variety. He felt exhausted, and remained at home several days longer than after an ordinary cold. Despite the added rest, he was quite tired when he resumed his normal activities. Several days later he complained of extreme fatigue. One evening he developed a tingling sensation in the tips of the fingers and toes and about the mouth. He was restless during the night and at 6:00 a.m. awakened and attempted to get out of bed but was very unsteady and fell backward against the bed. At this time his wife noticed that his speech was thick. There was ptosis of the right eyelid, and he complained of diplopia. His wife was obliged to help him to the bathroom because of the unsteadiness and the marked feeling of fatigue. His

physician examined him that morning and noted bilateral ptosis, some disturbance of eye movements and bilateral positive Babinski reflexes. That afternoon he entered a community hospital, when his physician noted more complete ptosis of the eyelids and reduced eye movements. There was bilateral weakness of the facial muscles, and the speech disturbance was more pronounced. The arms and legs were considered normal. However, the bilaterally positive Babinski reflexes persisted. He was seen in consultation six hours later, when he stated that he felt better, but complained of a sense of stiffness about the face. A nurse noticed that he had a progressively increasing difficulty in swallowing fluids during the afternoon and that he occasionally coughed because of inability to swallow the saliva. At no time were urinary bladder difficulties noted.

Physical examination revealed a slight cyanosis of the lips, but the lobes of the ears and the fingernail beds were normal in color. The respiratory movements of the chest and the diaphragmatic excursions seemed normal. Examination of the heart and lungs was negative. Neurologic examination showed bilateral, almost complete ptosis of the eyelids. Upward movement of the right eye could not be accomplished, but there was some movement laterally, medially and downward. The left eye moved through a slightly larger arc but was somewhat limited in all movements. The pupils were equal, with an aperture of approximately 1 mm., and reacted to light. The fundi were poorly visualized. The right optic disk was normal in size and outline, but hyperemic. Sensation of the cornea and skin of the face was normal. There was paralysis of the lower facial muscles, but the action of the frontalis was normal. The tongue was weakly extended in the midline to the edge of the lips. The palate lifted weakly in the midline. There was questionable weakness of the neck muscles, particularly the trapezius muscles, and the neck was not stiff. The abdominal reflexes were absent. The extremities were strong, and their movements well co-ordinated, as evidenced by the finger-to-nose and heel-to-shin tests. The tendon reflexes were hyperactive, and there were bilaterally positive Hoffmann and Babinski reflexes. No diagnosis was established, and the patient was immediately transferred to this hospital.

The family history was noncontributory. During World War I the patient suffered with influenza and was greatly debilitated by the illness, but there was no apparent permanent injury and no sequelae developed. During the subsequent years he contracted frequent upper respiratory infections, and many of these kept him from business.

During the months prior to the present trouble some general slowing-up of the patient's business activity was noticed but never to a degree considered important.

Physical examination confirmed the findings at the community hospital.

The blood pressure was normal. The temperature was 98.9°F., the pulse 69, and the respirations 26.

Examination of the blood revealed a hemoglobin of 13.6 gm. and a white-cell count of 18,000, with 87 per cent polymorphonuclears. When repeated four days later the white-cell count was 15,200. The blood nonprotein nitrogen was 28 mg. per 100 cc. The blood Hinton test was negative. The urine was negative. An x-ray film of the chest showed increased markings of the right upper lobe. There was no gross consolidation within the lung fields, and no displacement of the heart or mediastinum. A lumbar puncture showed an initial pressure of 160 mm. of water. The spinal fluid was clear and colorless and contained 400 red cells and 2 white cells per cubic millimeter. The total protein was 45 mg. per 100 cc.; the Wassermann was negative, as was the gold-sol curve. The chlorides were 723 mg. per 100 cc. Another spinal tap on the same day showed only 2 red cells per cubic millimeter.

That night he developed a distressing attack of hiccoughs, but at no time was there any respiratory difficulty. The following morning he felt and appeared improved. The left eyelid could be elevated more easily, and the ocular movements were better on both sides. The facial weakness had improved, and the tongue movements were better. Speech was less thick. The Babinski and Hoffmann reflexes gradually became negative during the second day. The tendon reflexes became somewhat sluggish, but strength remained good. Improvement continued during the next four days, and at the end of that time only the ptosis of the right eyelid and weakness of all the extraocular muscles remained. The strongest movement of the right eye was outward, and there seemed to be some dissociation in conjugate movements. The pupils were 3 to 4 mm. in diameter and reacted normally to light and accommodation.

On the evening of the fifth day, he again experienced some tingling of his fingertips and felt unusually tired. He slept well that night and ate a good breakfast the next morning. The attending nurse stated, however, that he was quite drowsy and less responsive than on the previous day. Approximately an hour after breakfast, when visited by his physician, he did not respond to a morning greeting. When approached more close-

ly, he mumbled, turned his head slightly to the left and "thickly" said that the numbness and weakness of his face had returned. At that time there were bilateral ptosis, a marked weakness of the lower facial muscles, inability to protrude the tongue and paralysis of the right hand and right leg. During the morning he became totally unable to speak but responded to pinprick by movement of the head and trunk. The left arm and leg could be moved on request. The pupils had again become very small. The neck muscles were weak. Tendon reflexes were more active on the right than on the left. The Babinski reflex was positive only on the left side. Respirations gradually became labored, and cyanosis developed. The patient began to drool. There was a marked tendency for periodic spells of hiccoughing and explosive coughing. On the seventh day, the temperature rose to 100°F., the bronchial tree filled with mucus, and the patient became very cyanotic and died.

DIFFERENTIAL DIAGNOSIS

DR. CHARLES S. KUBIK: The spinal fluid was negative except for a total protein of 45 mg., which is a moderate increase. I assume that the 400 red cells meant a bloody tap, since the fluid obtained at another puncture a little later contained only 2 red cells.

Ten days or so following the onset of what is said to have been an upper respiratory infection this fifty-two-year-old man rather suddenly began to have symptoms of cerebral disease. These progressed for a day or so and then improved somewhat; the patient seemed to be holding his own when he rapidly became worse, and died about one week after the onset of neurologic symptoms, or two and a half weeks after the time that his first illness began.

The description of the initial illness is too meager for one to attempt a diagnosis. It may or may not have been connected with what followed.

I should like to begin by discussing the cerebral symptoms, attempting first of all to make a localization, which, if it can be determined, sometimes gives a clue to the diagnosis. There were an abundance of focal signs, which were bilateral from the start, and most of these suggest disease of the brain stem. Ptosis, diplopia, ocular palsies point to the midbrain; bilateral facial weakness to the pons; dysphagia, inability to protrude the tongue, hiccough and weakness of the trapezii to the medulla. Involvement of the corticospinal tracts, indicated by extensor plantar responses, could occur at any one of these levels. It is not quite so simple, however, as I have made it sound. Why was only the lower part of the face para-

lyzed, and if there was nuclear facial and palatal paralysis, why was there no involvement of the fifth-nerve nucleus, with resulting sensory impairment on the face? One might have expected the vestibular nucleus to be implicated, with vertigo, nausea, nystagmus and unsteadiness of the extremities.

The rapidity with which symptoms developed at the time of the earlier episode and again shortly before death suggests arterial occlusion and infarction, and this diagnosis fits in with the blood supply of the parts under suspicion. The lateral portions of the medulla are usually supplied by branches of the posterior inferior cerebellar or vertebral arteries or both; its ventral and medial portions, by tiny branches of the anterior spinal and basilar arteries. The basilar artery supplies the greater part of the pons, and arising from its bifurcation are several small but important branches, which enter the midbrain anteriorly and supply, among other things, the third nerves, the region of third-nerve nuclei and at least part of the peduncles, through which the corticospinal tracts pass.

Since the optic thalami obtain their blood supply from the posterior cerebral or posterior communicating arteries or both, occlusion of the basilar artery might very well account for the paresthesia of fingers and toes and about the mouth. The posterior cerebral arteries also supply the visual cortex, and one might have expected impairment of vision or hemianopsia, although this would not occur if there was an adequate collateral circulation through the posterior communicating arteries. Small pupils are commonly observed with occlusion of the basilar artery.

Is remission consistent? We have observed it in other cases, and I believe that it may be explained by collateral circulation through the posterior communicating arteries. These are later blocked off by extension of the thrombus, when there is an exacerbation of the symptoms followed, in a short time, by death.

Rapidly increasing fatigue with subsequent cerebral symptoms might lead one to think of bacterial endocarditis, but there is nothing to support such a diagnosis. The onset of cerebral symptoms, moreover, which apparently was not altogether abrupt, was more suggestive of thrombosis than embolism.

DR. JAMES B. AYER: I am sorry that Dr. Kubik did not even consider the diagnosis that I made, and which to my surprise was wrong. This patient was of the right age to have contracted encephalitis lethargica, between 1918 and 1922, when this disease was epidemic. In one of the types of this disease it was not uncommon to see lesions

involving the brain stem, pathologically showing collections of small round cells and perivascular exudate, much of it in the gray matter, causing cranial nerve palsies; and it was characteristic of these palsies to vary in intensity and even to disappear during the course of the illness. The motor system was more affected than sensory. I should like to ask Dr. Kubik why he did not even consider this diagnosis.

DR. KUBIK: I did consider it but did not say anything about it. In a case we had here a good many years ago with paralysis of ocular muscles as the chief symptom but with a longer history,

cranial-nerve palsy on the right, the next day on the left, and the next day on the right again.

DR. KUBIK: As rapidly as in this case? There is usually a headache.

DR. AYER: Not necessarily.

DR. KUBIK: And drowsiness or confusion

DR. AYER: Usually.

DR. KUBIK: And cells in the spinal fluid

DR. AYER: Very few.

DR. KUBIK: Those were my reasons.

DR. DAVID G. COGAN: By the time I saw the patient on the second day of his hospitalization the eye movements had already improved. How-

FIGURE 1

there was extensive degeneration of the myelin in the midbrain, corresponding to what has been called "acute multiple sclerosis," although I am not sure it is not a misnomer. In that case there was extensive perivascular infiltration, suggesting an infectious process of some kind, but not encephalitis lethargica. One of my reasons for excluding encephalitis was the fact that there were remissions and exacerbations.

DR. AYER: It was quite characteristic to look at the encephalitic patient one day and to see a

over, at that time he showed a paresis of conjugate gaze downward, upward and to the right. Conjugate movements to the left were normal. The only evidence of ocular palsy was weakness of the right inferior oblique muscle.

DR. KUBIK: There was ptosis

DR. COGAN: Yes.

DR. KUBIK: On both sides.

DR. COGAN: Chiefly on the right. The fact that he had a paralysis predominantly of the vertical conjugate mechanism makes one think the lesion

was in the anterior tectum. But the conjugate palsy to one side points to a pontine lesion. My impression, therefore, was that the lesion was a diffuse midbrain and pontine affair involving the ocular conjugate tracts and nuclei and not a peripheral-nerve lesion.

DR. MILTON J. QUINN: I was greatly impressed by the signs of general weakness. The patient did complain that the right leg was weaker than the other over a period of two weeks following the respiratory infection. When I saw him he had a shaking chill, and following that, his temperature rose to 100°F. Examination of the pupils at that time showed the right to be 4 mm., and the left 2 mm.

CLINICAL DIAGNOSIS

Encephalitis lethargica, bulbar type.

DR. KUBIK'S DIAGNOSIS

Thrombosis of basilar artery.

ANATOMICAL DIAGNOSES

Thrombosis of basilar artery.

Infarction of pons and midbrain.

Pulmonary congestion and edema.

Pericarditis, aseptic, fibrinous.

Arteriosclerosis, moderate: aorta and coronary and basilar arteries.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The primary lesion in this case was, as Dr. Kubik predicted, a thrombosis of the basilar artery. Since most of us cannot visualize the details of the cerebral blood supply with the vividness that he does, I suggest that we look at the diagrams (Fig. 1) as I describe the findings. The thrombus began in the right vertebral artery just above the origin of the posterior cerebellar artery and extended upward throughout the length of the basilar artery to approximately the point

of its bifurcation to form the posterior cerebral arteries, the two arrows indicating its respective ends.

From this point on I wish that Dr. Kubik rather than I had to describe the anatomic findings, since I cannot reconcile certain discrepancies. In the fixed specimen the thrombus appeared to stop just short of the mouths of the superior cerebellar arteries, and it seems safe to infer that they must have remained functionally patent since there was no infarction of any portion of the cerebellum. On the other hand, there must have been at least partial occlusion of the little branches to the midbrain, since sizable areas of infarction were found in this region, as shown by the crosshatched areas in the upper cross-section diagram. There was, of course, extensive infarction of the pontine region, since the mouths of all the pontine branches were covered by the thrombus. This is shown in the middle cross-section diagram.

Judging from the clinical evidence we should have found infarction in the medulla as well, but neither grossly nor microscopically could this be demonstrated. It is possible, of course, that our sections were taken from too low a level.

DR. KUBIK: I suppose it is possible, also, that the symptoms from that area represented a pseudo-bulbar palsy owing to involvement of corticobulbar fibers at a higher level.

DR. MALLORY: The cause of the thrombosis was, I am sure, the usual one—arteriosclerosis. The basilar artery was sclerotic out of proportion to the condition of the other cerebral vessels. All the various communicating vessels of the circle of Willis were in excellent condition.

There was little of interest in the rest of the organs. The lungs showed the congestion and edema characteristic of a cerebral death. There was a slight fibrinous pericarditis, which was sterile, and we were unable to explain it. The endocardium was negative, and there was no obvious source for an embolus.

THE POSTCONCUSSIONAL SYNDROME

ELSEWHERE in this issue of the *Journal* there is
an article on the subject, "The Sequelae of War
Head Injuries," concluded from the previous issue
The author, Dr Derek Denny Brown, is the re-
cently appointed professor of neurology at Harvard
Medical School and holder of a captuncy in the
Royal Army Medical Corps Reserve As he points
out, the work was undertaken with the sponsorship
of the Directors General of the Army and Air
Force medical services and was actually carried out
at Oxford, England Dr Denny Brown was in
charge of the medical division of the hospital that
received casualties from both the above organiza-
tions The importance of this work can scarcely
be overestimated, and this country, and more es-

pecially the medical departments of the United
States Army and Navy, can learn much from it
besides the information that is written in the text
For his services in connection with this study
Dr Denny Brown received the decoration of O B E
from the British Government

In general the paper presents the English and
Continental viewpoint concerning craniocerebral
injuries, which differs in certain minor points from
the American For example, the neurosurgeons
of this country are prone to be somewhat more
practical in their approach they have, perhaps,
a somewhat wider conception of consciousness and
the loss of it,* and lean rather more heavily on
the accepted pathological definitions They are,
however, still badly befogged about an approach
to the problem of the postconcussional or post
traumatic syndrome, and in spite of a different
approach, this study can be made to serve as a very
useful proving ground for the solution of the
dilemma To be sure, the results cannot be ex-
pected to apply exactly to similar industrial accident
problems, because Dr Denny Brown did his work
among men under discipline, all of whom, it is
to be presumed, understood and spoke English
and all of whom certainly had an emotional and
psychologic approach and reaction to their dis-
abilities that of necessity differed from those of
civilians These are unimportant differences,
however, and are mentioned only to empha-
size the wide applicability and fundamentality
of his new and logical method of approach to this
problem He has finally provided a framework on
which to hang in proper order the different
psychologic, physical and emotional factors
that go to make up the confused whole
With this, he has also emphasized — prob-
ably for the first time — the importance of know-
ing the pretraumatic state under these various
categories as an essential to the understanding and
proper recognition of the post traumatic manifes-
tations

As implied above, another lesson can be learned
from the report of this study It is not included

*Cobl S. *Founda on of the op ych i rs* 331 p. Sc. d. c.

in the text but is implicit in the work as a whole. To collect sufficient material, to control its disposition during and after hospitalization and to achieve such results the patients on whom the work was carried out were concentrated in one hospital, which was "a combined services hospital for head injuries." In other words, all patients with cranio-cerebral injuries were taken to a hospital given over to the care of such cases and staffed by specialists in the appropriate line. This segregation of patients with a special type of injury has been practiced for some time in England, and such a scheme implies that appropriately trained surgeons and specialists are also segregated, not only for the benefit of the patients themselves, but also for the advancement of the science of medicine. Among such specialties, neurosurgery holds first place, and it is suggested that the Surgeons General of the United States Army and Navy go and do likewise. The plan would require little if any further dislocation of medical manpower, because many adequately trained neurosurgeons are already in service and are either doing nothing or practicing a specialty other than their own. Now is the time to prepare all over the country for proper care of the wounded in accordance with the special requirements of the wound. Valuable redeemable manpower should not be sacrificed for lack of a little foresight and of mental and organizational initiative.

INSTRUCTION CONCERNING THE TREATMENT OF GAS CASUALTIES

THE Medical Division of the Massachusetts Committee on Public Safety has arranged for state-wide instruction concerning gas warfare. As stated elsewhere in this issue of the *Journal*, the program will be given in each of the nine regional districts of Massachusetts by one of the three teams organized by Boston University, Harvard and Tufts medical schools.

The "course" will consist of a six-hour series of talks covering various aspects of chemical warfare, such as the chemistry of war gases, the action

of the lung-irritating gases and the vesicants, together with the diagnosis and treatment of lesions produced by them, organizational setups for medical decontamination, and group and individual means of protection.

Although protective measures, the identification of the gas used in a raid and the subsequent decontamination of buildings, streets and so forth are the functions of the Protection Division of the Massachusetts Committee on Public Safety, the treatment of gas casualties is solely the responsibility of the Medical Division, and all its members should become thoroughly familiar with the details of therapy. Chief and deputy regional directors, chief and deputy medical officers and physicians attached to medical first-aid posts are urged to attend the course and to pass on the knowledge thus gained to the personnel of their organizations.

MEDICAL EPONYM

SIBSON'S GROOVE

Francis Sibson (1814-1876), while resident surgeon and apothecary to the Nottingham General Hospital, published a paper, entitled "On the External Signs of the Position of the Lungs and Heart," in the *London Medical Gazette* (6:754-760, 1848). A portion of the article follows:

In the healthy robust man the well-formed chest has certain prominences and depressions indicating the organs underneath. . . . A depression crosses the seventh and sixth costal cartilages from the lower end of the sternum to the fifth intercostal space. These depressions are just below the thoracic prominences the right depression exactly indicates the lower margin of the right lung, while the left depression indicates the lower boundary of the heart.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1941 (Concluded)

There were 18 cases attributed to embolism that were associated with normal delivery. The first of these was that of a patient who entered a hospital with a temperature of 104°F., x-ray films of the

chest being negative. The second day after entry, pain developed in the right popliteal space; labor began shortly, and she was delivered normally; but death occurred suddenly several hours after delivery. Autopsy showed multiple pulmonary emboli.

The second patient had a normal spontaneous delivery five minutes after hospital entry. Four days later a septic temperature developed and sulfonamide therapy was instituted. This was apparently successful, for the patient was discharged nine days after delivery, the highest temperature for the two days before having been 99°F. One week later she returned to the hospital complaining of pain in the abdomen, and the following day her temperature rose to 104°F. Transfusions were given and sulfonamide therapy repeated; pelvic examination suggested a pelvic phlebitis. Death was sudden, and a diagnosis of septic emboli was made by x-ray examination.

The third case was that of a patient who was not hospitalized, sudden death occurring a month after delivery. The medical examiner made a diagnosis of pulmonary embolism, although no autopsy was performed. It was known that the patient had phlebitis of the left leg.

The fourth patient was an elderly primipara who developed a temperature of 100°F. on the fifth post-partum day, after which mild phlebitis of the left leg developed. The temperature never exceeded 99°F. during her hospital stay. She was allowed out of bed on the ninth day after delivery and complained of severe pain in the right leg. She was allowed up again, however, on the following day, and was about to be discharged when she suddenly collapsed and died. This case was not intelligently handled, and it is quite possible that surgical consultation at the first sign of phlebitis would have resulted in venous ligation and the prevention of this catastrophe.

The fifth patient was delivered spontaneously after a normal labor and had an uneventful convalescence. She was discharged from the hospital at her own request nine days post partum but collapsed shortly after reaching home and died while being conveyed back to the hospital. Although there is no history of phlebitis it may have existed.

The sixth case was that of a patient who had previously had two erythroblastic babies, associated with mild toxemia. The third pregnancy was complicated by increased blood pressure, and albuminuria appearing at about the thirty-fifth week. After six days in a hospital the membranes were artificially ruptured, and normal delivery of an erythroblastic infant, weighing 6 pounds, 9 ounces followed. Convalescence was normal until the sixth post-partum day, when sudden death occurred following an acute pain in the chest.

The seventh patient had an uneventful convalescence following a normal delivery until the seventh post-partum day, when her temperature rose and continued septic for two weeks. Sulfathiazole eventually resulted in subsidence of the fever. While "sitting up in bed and talking" the patient fell back and died within three minutes. The embolus probably originated in the pelvis.

The eighth patient was allowed out of bed ten days following a normal delivery, her convalescence having been uneventful. Death occurred almost instantaneously.

The ninth case was that of a patient who, after a normal delivery and an afebrile convalescence, had a sudden pain in the chest while walking about on the ninth post-partum day; she died within a few minutes. In view of the fact that there was no evidence of phlebitis, it is possible that the embolus arose from the pelvic veins. It is hard to see how such a catastrophe could have been averted if the report of the case is accurate.

The tenth patient went home against advice ten days post partum, having had a slight fever during convalescence. On getting up the following morning, she died suddenly.

The eleventh patient had a convalescence that was complicated by a temperature of 100°F. on the seventh and eighth post-partum days, when pain in the left chest was noted. The temperature was normal during the rest of her hospital stay, and she was discharged a week later. Four days later a phlebitis developed and she was put to bed, but death occurred while she was sitting up in bed drinking a glassful of water. This case again emphasizes the advantage of surgery in certain types of phlebitis.

The twelfth patient, following a normal delivery, had an uneventful convalescence until the eighth day post partum, at which time the temperature ranged from 99.6 to 100.6°F., the slight fever continued until death, which occurred suddenly seventeen days after delivery. During this time there was clinical evidence of a phlebitis, which was treated conservatively by the use of ice. In this case, also, surgical intervention might have been advantageous.

The histories of the remaining 6 cases are inadequate. One record was never received because the patient's family and doctor had moved away and could not be located. The death certificate, however, attributes the death to albuminuria and puerperal embolism. The other 5 patients were delivered normally, one prematurely at seven months. In 4 cases, death occurred almost immediately after delivery, and one of these patients had a massive collapse of the lung. In the fifth

the lesions, either progressive or regressive, and positive sputum.

Twelve of the patients with positive sputums were over fifty years of age. None of these had marked symptoms at the time the tubercle bacilli were discovered, and some have remained symptom free during two years of observation. In such cases, reactivation may await some new strain, such as an extra physical load imposed on the worker who enters war industry. This is a risk for the healed or arrested case as well.

It is not known whether the higher incidence of tuberculosis in the elderly which we have encountered in a group of unemployed also occurs in elderly persons of higher income levels. Since mortality tables are prepared from deaths at all strata, it would seem possible that this may be the actual state of affairs. In any event, it is of the utmost importance to devote a greater portion of our efforts in tuberculosis case-finding to the discovery of the elderly individual with tuberculosis. This should be done without lessening case-finding measures in young persons, as the latter comprise a larger proportion of the population. Consequently, although the percentage of tuberculosis may be less in those of younger years, the absolute number of cases undoubtedly is greater.

More emphasis should be placed on the examination of all possible sources of a newly diagnosed case of tuberculosis. Even when the older members of a tuberculous household appear to be in the best of health, they should be x-rayed. When a thorough search of the immediate family of an affected person fails to reveal the source of infection, further inquiries should be made as to the identity of others with whom he has most frequent contact, and examination of these persons should be arranged.

The physician should also always suspect tuberculosis in all his elderly patients who have even mild pulmonary symptoms, and should take the necessary steps to rule out this disease before making a final diagnosis.

The most productive method of case finding among the elderly would seem to be the x-ray survey of such population groups. The survey detailed in this paper serves to illustrate the value of such a procedure. Similar surveys concentrated on the older fraction of the population, particularly males, would, we believe, disclose many unknown spreaders of tuberculosis who have been acting as reservoirs of disease in their communities. — Reprinted, in part, from *Tuberculosis Abstracts*, November, 1942.

REPORT OF MEETING

NEW ENGLAND PATHOLOGICAL SOCIETY

A regular meeting of the New England Pathological Society was held on March 19, 1942, at the Peter Bent Brigham Hospital. The program was presented by the Department of Legal Medicine of the Harvard Medical School.

The first paper, "The Law and the Pathologist," was presented by Dr. Hubert W. Smith. He said that, around 1300, the law school at Bologna induced doctors to open dead bodies to determine the cause of death in medico-legal cases. Law was thus father of forensic pathology and the grandsire of orthodox pathology, which subsequently applied like methods to study of disease.

At common law no right of property is recognized in dead bodies, but the surviving spouse, or secondarily the next of kin, has a right to possession of the body, intact as at death, for burial. An unauthorized autopsy invades this right and makes a pathologist liable in damages for mental anguish caused thereby, and jury awards tend to be substantial. Without statute, no privilege exists to perform unconsented autopsies to complete death certificates. Oral or written consent suffices, but as in surgical operations, reasonable mistake does not protect if actual consent is wanting. Conditions can be imposed on consent. Bare consent to autopsy impliedly authorizes retention of microscopic sections but not of gross organs. Jurisdiction of coroners to order autopsy exists only if criminal causation of death is reasonably suspected; orders to aid insurance investigations are void and do not protect the pathologist. Accident policies usually require that the insurer have notice and opportunity to attend autopsies, the beneficiary's innocent violation may forfeit the insurance. Whether a person can authorize an autopsy on himself by contract or will is still controversial. To protect himself here the pathologist should require consent of the next of kin or his employer's agreement for indemnification.

Liability for negligent diagnosis may arise from negligence in identifying the disease or in assuming to diagnose on an improper preparation or specimen.

Pathologists who supervise production of biologic materials may risk liability for injury to remote users due to negligent contamination in manufacture. To prove due care, Dr. Smith advised that aseptic techniques be used, that proper cross-checks and contamination tests be done on random samples, making certain that samples of large batches are retained under sterile conditions to show the product was pure when distributed, that proper labels be used, that known risks inherent in the product be adequately disclosed and that full records covering production and distribution be kept.

The second paper, "Changes in the Magnesium and Chloride Content of the Blood following Drowning in Fresh and Sea Water," was presented by Drs. Walter W. Jetter and Alan R. Moritz. Because the pathological findings after death from drowning are so frequently inconclusive, opinions regarding the cause of death of persons whose bodies have been recovered from water are usually based on negative rather than positive evidence. It has long been known that the electrolyte content of the heart's blood of drowned persons may be altered, and it has been suggested that such changes are pathognomonic of death by drowning. The extent to which the electrolyte concentration in post-mortem samples of blood may show change as a result of causes other than drowning has not been investigated, and experiments were undertaken to determine the significance of such changes in relation to drowning.

Changes in the concentration and distribution of chlorides and magnesium were studied in four groups of dogs. In the first, the animals were sacrificed by mechanically induced asphyxia (not drowning) and allowed to remain in the open air for as long as seventy-two hours after death. The rate of post-mortem change in these animals was regulated by keeping their bodies at different temperatures. In the second group, the animals were sacrificed by mechanical asphyxia and were then submerged in either fresh or sea water throughout the period of post-mortem observation. In the third group, the animals were drowned in fresh water; and in the fourth, they were drowned in sea water. Blood was withdrawn from

the right and left sides of the heart at intervals after death, and the chloride and the magnesium content of both cells and plasma were observed

In the control animals, it was found that diffusion of both chlorides and magnesium between cells and plasma began soon after death and that within twelve hours the normal ante mortem differences in their concentrations in cells and plasma had usually almost entirely disappeared. The chloride content of heart's blood underwent progressive reduction during putrefaction, whereas the magnesium content became progressively higher. Submersion after death did not alter the rate or character of these changes

In animals dead of drowning in fresh water there was a sharp drop in the chloride content of the blood in both sides of the heart during the agonal period. The reduction was greater than that observed in any of the control animals. The reduction was more pronounced in the left than in the right side. The difference between the concentrations in the two sides of the heart diminished as putrefaction progressed. Marked hemolysis of left ventricular blood was observed within fifteen minutes after death

In animals dead of drowning in sea water it was observed almost immediately after death that both the magnesium and the chlorides in the heart's blood were elevated, the former proportionately more than the latter. The elevation was more pronounced in the left than in the right side of the heart. Hemolysis of blood was delayed, and the magnesium content of the stomach was abnormally high.

In the discussion Dr. Moritz stated that he had applied the results of these experimental animals in several cases in human drownings, and that he had found these data distinctly useful

The third paper, "Adaptive Intimal Changes Which Occur in Arteries following Localized Circulatory Stasis," was presented by Dr. Alan R. Moritz. Varying degrees of local stasis were induced in segments of carotid, brachial and femoral arteries of dogs by means of clamps and ligatures. The degree of stasis varied from complete isolation of unbranched segments of vessels by ligation and section to the application of a single partially obstructive clamp. Segments of arteries were excised for histologic examination at intervals ranging from a few days to a year after operation. Several types of reactive change were observed. Thrombosis occurred in the segments in which the flow of blood had been completely obstructed. In some dogs the thrombi organized and remained completely occlusive, and in others the thrombi became canalized and the obstructions were bypassed. In arteries that had been severely but incompletely obstructed, thrombosis occurred near the sites of ligation or clamping, and intimal proliferation not accompanied by thrombosis produced permanent narrowing of the central portion of the segment in which relative circulatory stasis persisted. In segments of arteries in which the reduction of blood flow was not sufficiently severe to result in thrombosis, two types of reaction were observed. In some the lumen of the affected segment became and remained narrowed by contraction without significant alteration of the intima. In others such functional adaptation to reduced blood flow was accompanied by reactive intimal proliferation. New elastic fibers formed in the hyperplastic intima, and the changes in these vessels were in many respects similar to those that occur in the umbilical arteries of young infants in the first few months after birth, in the uterine arteries of young women during the postpartum period, in the arteries of the ovarian cortex during the catamenial

period of life, in the intermediate and small arteries of the kidneys of persons suffering from certain forms of chronic Bright's disease and the splenic arteries of infants and children following splenectomy

The results of this study suggest that certain of the arterial and arteriolar lesions heretofore regarded as primary may actually represent a secondary adaptive reaction to reduced blood flow incident to destructive or involutional parenchymatous change.

In the discussion Dr. B. E. Clarke asked, if all these changes are adaptive, how Dr. Moritz explained changes in the placenta during pregnancy where there is a similar process taking place, although the placenta is growing. Dr. Moritz stated that he did not know but that he did not believe that the changes in the uterine and ovarian arteries are entirely adaptive.

In answer to Dr. M. J. Schlesinger's question whether this adaptive change is better in young people because of the abundance of new smooth muscle and elastic tissue that is being laid down, the speaker replied that there is no age relation, so far as the dog is concerned. In human beings, however, the best changes were seen in the splenic arteries following splenectomy. The vessels of young people are best because they are likeliest to have no pre-existing intimal change.

The fourth paper, "Medicolegal Tests for the Identification of Seminal Fluid," was presented by Dr. O. J. Pollak. The evaluation of tests for semen is based on the definition of rape by law. Recovery of semen presents supporting evidence, together with genital, perigenital and remote injuries on the person of the victim and the suspect.

Male ejaculate may be found in the female genitals, on the body or on objects. Motile spermatozoa may be detected in the vagina up to three hours, in the cervix up to one hundred hours, and immobilized spermatozoa in the vagina up to twenty-four hours and in the cervix up to seven and a half days after intercourse. No conclusions are allowed as to the time elapsed after copulation or after death.

Outside the genitals, semen dries and often is absorbed by the soiled material. Stains are detected by ultraviolet rays of chemical indicators. From fresh material, films are made and stained with Giemsa's stain. Findings are tabulated in a spermogram and in biometric curves. If the material is dried, complete mechanical destruction by teasing the fabric into finest shreds and subsequent staining, or chemical decomposition in concentrated sulfuric acid and examination of the residue are the two ways leading to the recovery of spermatozoa. Positive findings in fabric boiled in water for twenty minutes demonstrate that spermatozoa firmly adhere to the support. This explains the failure of other methods.

If no spermatozoa can be found, immunological methods may reveal the true nature of a stain. The often recommended microchemical tests are neither sensitive nor specific. Material is differentiated from animal substrate and identified as semen by precipitin tests performed with antihuman semen serum after absorption with human blood. Grouping of semen and semen stains with the absorption technique is invaluable for establishing semen individuality provided that it is carried out under proper controls and with criticism.

In the discussion Dr. Moritz emphasized the point that, from a medicolegal standpoint, by far the most valuable scientific evidence is provided by the demonstration of the spermatozoa and added that all methods should be tried to demonstrate the spermatozoa before

resorting to the immunologic method, which is a complicated procedure. The average juror is happier if shown a photograph of the spermatozoa than if confronted with complicated tests that require the immunization of animals.

The fifth paper, "An Experimental Investigation of the Stability and Distribution of Carboxyl Hemoglobin after Death, with Particular Reference to the Difficulties Sometimes Encountered in Incinerated Bodies," was presented by Dr. Herbert S. Breyfogle. Attention was called to three problems incident to medicolegal investigation of suspected carbon monoxide inhalation. First, the presence of carbon monoxide in burned bodies is important in the proof that a person was alive when exposed to flames. Burning, however, may reduce the blood to a solid coagulum, presenting a technical difficulty in the detection of carbon monoxide; however, a qualitative method was described for the detection of carbon monoxide hemochromogen in such blood, which also permits the recovery gasometrically of small amounts. Secondly, the presence of carbon monoxide in extravasations of blood resulting from injury is important in determining whether an injury preceded or followed inhalation of carbon monoxide. Cases were cited showing the value of this information, and experimental studies were presented indicating that carbon monoxide-free hemorrhagic extravasations do not take up the gas from circulating blood rich in carbon monoxide and that post-mortem diffusion of carbon monoxide following fatal asphyxia by this agent does not occur. Finally, the relation of carbon monoxide and putrefaction was discussed. Various claims made in the literature indicate that carbon monoxide may be demonstrated for as long as twenty months after death, regardless of the state of the cadaver; however, in dogs asphyxiated with carbon monoxide and left at room temperature up to seventy-two hours there was a gradual decline in the saturation of carbon monoxide amounting to 5 per cent every twenty-four hours. Control studies indicated that carbon monoxide is not ordinarily generated incident to the putrefaction of animal tissue.

In the discussion Dr. W. J. Brickley stated that if the buried body has already been embalmed, it is best to examine blood from the iliac arteries for carbon monoxide because usually the embalming fluid does not reach these arteries so easily. Dr. Clarke reported that he had studied the blood removed from 24 people who had been found in burned houses, and in three cases in which no carbon monoxide was found, it was discovered that a deliberative attempt had been made to dispose of the body by burning. Two men had been shot, and the third had been hit over the head. All the rest showed a relatively high carbon monoxide content. This matter is of considerable practical importance in the investigation of bodies found in basements of burned houses.

In closing the speaker stated that if embalming does take place immediately post mortem, some blood may be preserved.

The last paper, presented by Dr. J. C. Bequaert, was entitled, "Some Observations on the Fauna of Putrefaction and Its Potential Value in Establishing the Time of Death." On animal and human corpses, from the time of death until the final disintegration of all tissues, except the bones, there is a definite and orderly succession of arthropods (insects and mites) feeding on the tissues. Each species arrives at a certain stage of decay, to be replaced by one or more others at the next stage. The duration of each stage and the species of arthropods present vary with the nature of the dead body, the climate, the sea-

sons, the condition of exposure or burial, the locality (whether city or country) and the region of the earth. All these factors must be properly studied before reliable medicolegal conclusions can be drawn from some particular arthropod found on a corpse. Few such studies have been made thus far, the most complete to date being those of Megnin in Central France. This investigator recognized on a human corpse left in the open eight types or "squads" of necrophagous arthropods succeeding one another at the following eight stages of decay: fresh or recent corpse; early putrefaction; butyric fermentation; caseic fermentation; ammoniacal fermentation; mummification of tissues; removal of dried tissues and hairs; and skeleton. As each of these stages lasts a certain time, Megnin claimed to be able to deduce the time elapsed since death occurred from the species of arthropods found with the corpse when it was discovered. He described a number of cases in which his method was applied and pointed out that in some of them confessions by the criminals involved proved that he was correct. In America, Johnston and Villeneuve (1897) investigated the fauna of freely exposed cadavers in southern Quebec; and Motter (1898) studied the arthropods found after exhumation. From 1894 to 1897, the late Dr. Garry deN. Hough, of New Bedford, did considerable research on the fauna of dead bodies, but his findings were never published. Dr. Bequaert concluded with a discussion of the arthropods found on two corpses discovered in the open in Massachusetts.

BOOK REVIEW

Science and Sanity: An introduction to non-Aristotelian systems and general semantics. By Alfred Korzybski. Second edition, with a supplementary introduction and bibliography. 8°, paper, 842 pp., with 95 illustrations. Lancaster, Pennsylvania: The International Non-Aristotelian Library Publishing Company, 1941. \$6.00.

The second edition of this suggestive and most provocative book will make a serious appeal to those who deal, or wish to deal, with the psychologic reactions of a given person to words and language and other symbols and events in connection with their meanings. "Meaning" for this author must be considered as a multiordinal term as it applies to all levels of abstraction; the concept of multiordinality is inherent in the structure of "human knowledge." The main thesis of the book revolves about the concept that the Aristotelian "laws of thought" formulated as the law of identity, the law of contradiction and the law of the excluded middle, were satisfactory for an earlier epoch but are no longer productive of sanity for these times. What is needed is a new non-Aristotelian system completely free of these laws.

The author builds an interesting diagram of a "structural differential" necessary for one to receive full semantic benefit, since if one is to differentiate he cannot identify. The argument is forcibly presented that to achieve sanity one must study the structural characteristics of this world first, as scientists do, and only later build languages of similar structure. Illustrations are drawn from the fields of mathematics, physics and biology to support the author's thesis. The book is not easy to read, but when one has once done so, it will surely lead to a second reading and increased profit. The first appearance of this book stimulated the establishment of courses covering the topic in certain universities.

HEMOLYTIC TRANSFUSION REACTIONS DUE TO THE Rh FACTOR: A PREVENTABLE DANGER*

LOUIS K. DIAMOND, M.D.†

BOSTON

WITH the modern technic of grouping and cross-matching the bloods of donors and recipients, hemolytic transfusion reactions due to incompatibilities involving the A and B agglutinogens are exceedingly rare. In an analysis of more than 3000 transfusions Wiener et al.¹ found only two such reactions due to gross incompatibility. However, the occurrence of hemolytic transfusion reactions in spite of the use of blood of the proper group—that is, due to intragroup incompatibilities—has recently aroused much interest. An important step toward eliminating such hemolytic reactions and preventing serious if not fatal kidney insufficiency from transfusion of incompatible blood has been the discovery of the Rh agglutinin of human red blood cells and the modes of development of an anti-Rh agglutinin in the serum of persons lacking this red-cell factor.

In 1939, Levine and Stetson² reported an unusual case of intragroup incompatibility and first called attention to the role of the fetus in causing isoimmunization in a pregnant woman. In 1940, Landsteiner and Wiener³ described an agglutinable factor in human blood demonstrable by immune serums produced against the red cells of the Indian macaque (*Macaca rhesus*). This agglutinin, called the "Rh (rhesus) factor," was later proved by the same workers⁴ to be present in the red cells of about 85 per cent of the white population (Rh+ persons) and absent in about 15 per cent (Rh- persons).

In 1940, Wiener and Peters⁵ described hemolytic reactions following transfusions of blood of a homologous group. In 3 cases the Rh factor was involved. Also in 1940, Levine and Katzin⁶ described the varieties of isoagglutinins that may result from isoimmunization in pregnancy, and pointed out that the specificity of one serum con-

taining "warm" agglutinins corresponded to the anti-Rh agglutinins of Landsteiner and Wiener.³ The following year, Wiener⁷ published further observations on hemolytic reactions involving the Rh factor, with and without demonstrable antibodies.

In a timely warning, Levine⁸ stressed the frequency of transfusion accidents in pregnant women, stating that the Rh factor was the antigenic agent in the great majority of cases. He also pointed out that a modified compatibility test might aid in the detection of incompatibilities. For this test, a mixture of donor's cells and recipient's serum in a test tube is incubated at 37°C. for a half to one hour, centrifuged for one minute and examined for agglutination.

By these and further steps, Levine and his associates⁹ and Wiener demonstrated the importance of the Rh factor and of the development of anti-Rh agglutinins in recipients as the cause of previously baffling intragroup transfusion reactions.

Since these pioneer investigations, there have been a number of case reports of reactions involving the Rh factor and anti-Rh agglutinins.¹⁰⁻¹³

An important corollary of the investigations by Levine and his associates^{14, 15} of the presence of an anti-Rh agglutinin in the serums of pregnant women suffering intragroup transfusion accidents was their discovery of the role of the anti-Rh antibody in the pathogenesis of erythroblastosis foetalis in the offspring. The presence of an Rh+ fetus (this blood factor being inherited from the father as a dominant characteristic) in an Rh- woman may, in a small number of matings, permit the passage of Rh+ blood cells into the maternal circulation, with resultant isoimmunization and the development of an anti-Rh agglutinin. This, being a soluble component of the serum, enters the fetal circulation. When present in sufficient concentration over a period of months, the anti-Rh agglutinin, acting on the Rh+ cells of the infant, may cause jaundice, anemia, overproduction of nucle-

†Assistant professor of pediatrics, Harvard Medical School, visiting physician, Children's Hospital.

ated red cells and all the other signs and symptoms of the condition known as erythroblastosis foetalis.

Transfusion reactions occurring in 10 cases serve as the basis for this report. In every case the recipient was found to have received blood compatible according to tests for the blood groups, but incompatible with regard to the Rh factor; that is, the donor's blood was Rh+, whereas the recipient lacked the Rh factor and had had a means of isoimmunization previously, leading to the development of an anti-Rh agglutinin. In another patient (Case 11), an anti-Rh agglutinin was demonstrated early and a transfusion reaction was avoided.

METHOD OF TESTING

The method of testing for the Rh factor, as described by Levine et al.,¹⁵ consists of making a 2 per cent (roughly) suspension of the unknown erythrocytes in normal saline solution, placing 2 drops of this suspension in a 7-mm. test tube (Kahn type), adding 1 or 2 drops of the neutralized* anti-Rh serum, incubating for about 1 hour in a water bath, at 37°C., centrifuging at about 500 revolutions for 1 minute and then by gentle agitation resuspending the cell button formed on the bottom of the tube. Gross clumping is visible to the naked eye or, if the clumps are smaller, through a hand lens. The doubtful and apparently negative reactions are checked by examination of a drop placed on a slide under the microscope. Landsteiner⁴ has advised judging the positive reactions by examination of the cell button for smoothness or irregularity, but for the inexperienced observer the microscopic examination seems easier. Rh+ cells often are clumped at the end of 15 minutes or less of incubation. If haste is essential, the test can be set up in duplicate and placed in the warming bath. At the end of 15 minutes, one tube is centrifuged and the test read. If negative at this time the incubation of the other tube is continued for the full hour, before a final reading is made.

Since according to Levine[†] the Rh factor is a complex antigen, and the human serums used for typing are the result of specific immunization with one or another Rh+ cell, it is necessary to know beforehand how specific the testing serum is, and in many cases to use more than one anti-Rh serum. As a rule, at least two serums are used, one which yields about 70 per cent positive reactions, and the other about 87 per cent. To date, serums produced experimentally in laboratory animals have not been satisfactory or available, and only human serums have therefore been used. Only a small percentage of Rh-human beings, when immunized by transfusions of Rh+ blood or by pregnancies involving a fetus having the Rh factor, develop anti-Rh agglutinins. Often these give weak reactions in vitro, even though the in-vivo reactions may be marked, and the titer if high remains so for only a short time after the transfusion reactions or the termination of the pregnancy that stimulated the isoimmunization. For these reasons, sources of anti-Rh serums of high titer are difficult to find.

In testing an unknown serum for the anti-Rh agglutinin, it is advisable to use known Rh+ cells from different persons, choosing Group O erythrocytes or those of the same group as the unknown whose serum is being tested. To avoid missing a weak agglutinin or obtaining questionable readings and to determine the specificity of the anti-Rh serum when it is present, it has been found best to use at least ten samples of Rh+ cells, each of a different antigenic composition. The mixtures of cells and serum are incubated, centrifuged and read as described above.

CASE REPORTS[‡]

CASE 1. A 45-year-old man with aplastic anemia had received four transfusions of compatible blood 5 months previous to admission, without a serious reaction. At the present entry a Group O donor was used, who by the usual cross-matching technic was apparently compatible. A moderate reaction to this transfusion resulted, with pain in the flanks, mild hemoglobinuria, fever and jaundice and with no apparent improvement in the anemia. A second transfusion, immediately following the first, produced a severer reaction.

Re-examination of the patient's and the donor's blood samples, taken within a few hours after the last reaction, showed each to be Group O. The donor's cells were strongly Rh+. A test of the recipient's cells with anti-Rh serum produced gross clumping. However, microscopically the clumps were large but rare and most of the cells were unagglutinated. It seemed probable, therefore, that the recipient's blood contained a mixture of Rh+ (donor's) and Rh- (recipient's) cells. Test of the patient's serum showed no anti-Rh agglutinin at this time.

Two transfusions of Rh- blood were given, with no reaction and with a satisfactory rise in the erythrocyte and hemoglobin values. Another test of the patient's serum, 11 days after the reaction, showed slight but definite clumping of Rh+ cells.

Ten more transfusions of Rh- blood were given in the following 4 months, with no untoward effects.

CASE 2. A 30-year-old man with massive hemorrhage from a duodenal ulcer was given multiple transfusions. At the end of the fourth transfusion, a slight febrile reaction was noted. The fifth transfusion was followed by a severe reaction and evidences of hemolysis.

Blood from the last donor and from the recipient taken 2 hours after this reaction showed the donor's cells to be Group O and Rh+, and the patient's cells likewise Group O, with some gross clumping in the anti-Rh serum. Microscopically the majority of the cells were single, there being only a few large clumps. This suggested a mixture of Rh+ and Rh- cells. Tests for the anti-Rh agglutinin in the patient's serum were negative at this time. A transfusion of Rh- blood was given, with a satisfactory response.

Retesting of the patient's blood 11 days after the reaction showed the red cells to be definitely Rh-. The serum failed to agglutinate any of ten different Rh+ cell samples.

CASE 3. A 12-year-old girl with profound anemia from bleeding intestinal polyps was given two transfusions, with

*Neutralized with Witebsky soluble A and B factors, obtained through the courtesy of Dr. Witebsky and the Eli Lilly Company, Indianapolis.
†Personal communication.

‡Cases 1, 2, 3, 5 and 6 are from the files of the Blood Grouping Laboratory, an organization formed by the Boston Lying-in Hospital, the Massachusetts Memorial Hospitals and the Children's Hospital for the purpose of typing blood for the Rh factor, investigating transfusion reactions and procuring suitable donors on demand.

no untoward reaction. Two weeks later, another transfusion with matched compatible blood was administered but was followed by a severe hemolytic and febrile reaction. A specimen of the 1st donor's blood and a sample of the patient's blood taken after the reaction were obtained. The donor's cells were Group O and strongly Rh+. The recipient's Group O cells likewise had some clumping grossly, but under microscopic examination the clumps were scarce though large, and most of the cells were unagglutinated, suggesting the presence of some Rh+ cells in an Rh- person. Further confirmation of this was found by tests for the M and N factors. The donor's blood was Type M, the mixed blood showed both M and N cells, the patient's blood at a later test was Type N and Rh-. Tests for the anti Rh agglutinin in the recipient's serum showed none present in the first sample but a definite trace detectable two weeks later.

Rh- blood was used for a subsequent transfusion, with no untoward reaction.

CASE 4* A 54-year-old woman had had four uncomplicated pregnancies from the ages of 19 to 30. She was known to be suffering from chronic anemia and had received her first transfusion of 600 cc. of blood from her husband in April, 1937, with no reaction. In October 1940, a second transfusion of blood from her husband was given but had to be discontinued after only 325 cc. had been administered, because of a chill and sudden fever. In December, 1940, a diagnosis of congenital hemolytic jaundice was made for the first time, and on January 4, 1941, in preparation for splenectomy a third transfusion of 500 cc. of blood from a friend was given with no reaction. On January 7, the husband was again tried as donor for a fourth transfusion, since ordinary cross-matching showed no incompatibility. After 200 cc. of blood had been given, a severe hemolytic reaction occurred, with hemoglobinemia, hemoglobinuria and fever. The next day a friend was used for a fifth transfusion and again, after 300 cc. had been received, the patient had a severe hemolytic reaction similar to that of the previous day. The patient was finally subjected to splenectomy on January 31, and during and after operation a sixth transfusion of 500 cc. from a friend and a seventh from her brother were given in immediate succession. The latter transfusion had to be halted after 300 cc. of blood had been used, owing to a chill and a high temperature, although no hemoglobinuria developed. Despite this, the patient made a fair recovery and has been well since.

Subsequent typing of the patient's and the various donors' bloods revealed that the husband's cells were Group O (M and N factors) and Rh+, whereas the wife's were Group A (M factor) and Rh-. Of the donors, the blood used for the third transfusion, at which time no reaction occurred, was Group O (M and N factors) and Rh-. All the other bloods given were Rh+, and the transfusions were followed by reactions. The first two, from the husband, were presumably the stimuli for immunization. No anti Rh agglutinin was detected 2 days, 11 days, and 11 months after the hemolytic reactions.

CASE 5 A 5-year-old boy was admitted with the diagnosis of chronic progressive nephritis in a nephrotic crisis,

with marked generalized edema, ascites and a lowered serum protein level. No transfusion had been given previously. In preparation for transfusion the patient's blood was matched against that of two donors, both Group O, as was he. In the cross-matching, the donor's cells showed slight clumping in the recipient's serum but there was no clumping of the patient's cells in the donor's sera or in his own serum. Further studies revealed that both donors were Rh+ and the patient Rh-, and that his blood serum agglutinated seven samples of Rh+ cells but none of Rh- cells. The clumping was present to a slight extent at room temperature, and more definitely after incubation for an hour at 37°C. Accordingly, a transfusion of 300 cc. of blood from an Rh- donor was given. No untoward effect was seen.

During the ensuing 3 months, six transfusions of Rh blood were given, without reaction.

CASES 6, 7, 8 and 9 These patients were essentially alike in that each was a young multipara (the ages being 22 to 34 years) who had had no previous transfusions but had given birth at a second pregnancy to an infant with erythroblastosis foetalis. A transfusion administered at the time of or shortly after this delivery had been followed by a hemolytic reaction.

Tests on the bloods of the mothers showed that each was Rh-. In every case, the father and the children were Rh+. Anti Rh agglutinins were detected in the serum of each recipient. One or more transfusions with Rh-compatible blood were then given, with no untoward reactions.

CASE 10† A 19-year-old woman was delivered of a stillborn infant, which showed clinically congenital hydrops and pathologically all the criteria of erythroblastosis foetalis. Since such an occurrence in association with a first pregnancy is extremely rare a careful investigation of the patient's past history was made, with the following results. Three and a half years previously, the patient had required repeated transfusions after the removal of a chest tumor. In 2 months six transfusions were given, the patient and donors being Group O and compatible by cross-matching,—with no unusual reaction. About 2 years later, a thoracoplasty was done and the patient was given four more transfusions in 4 days. The last two of these were followed by moderately severe reactions. The patient made a good recovery, was married twice, pregnant and delivered the hydropic infant mentioned above.

Tests on the blood of the patient's husband (reported as a donor for her) showed him to be Group O. The patient herself was Group O and Rh-. The donors used for her last two transfusions (last two reactions) 20 months previously were both Group O Rh-. Tests for anti Rh agglutinins were negative.

CASE 11‡ A 41-year-old woman was delivered of a sixth child, which shortly after birth developed erythroblastosis foetalis, with marked edema and jaundice. The obstetric history was most important. Her first two pregnancies had ended in the delivery of stillborn infants who had continued entirely well. The third pregnancy had been cesarean section because of fetal distress. The infant had died of

*This case with its interesting and initially baffling transfusion reaction was included in the series reported by Wiener¹ (Case 9). The more complete studies were carried out recently in co-operation with Dr. T. Hale of the Thorne Medical Research Laboratory, Boston City Hospital to whom I am indebted for this report.

†Permission to publish this case is being given by Boston.

‡Dr. Paul Gustafson of Boston supplied the details of this case.

tion revealed no evidence of erythroblastosis foetalis. After the operation the mother received a transfusion from an apparently compatible donor (later proved to be Rh+) and had no reaction. During the sixth and last pregnancy the patient developed signs of mild eclampsia and went into active labor at the end of the 8th month, with the result mentioned above.

After the delivery, palpation revealed a tear in the muscle of the uterus. Hysterectomy was therefore done. Following this, four successive transfusions of apparently compatible blood were given, each being followed by greater collapse, and then hemoglobinuria, hemoglobine-mia, jaundice and finally almost complete anuria. In the following 10 days, three more transfusions of known Rh- blood were given, with no untoward reactions. Alkalinization therapy and decapsulation of the kidneys were carried out, but the patient succumbed to uremia and terminal infection.

Grouping and typing of the patient's blood after the fourth transfusion showed her to be Group O and Rh-. A strong titer of anti-Rh agglutinin was easily demonstrated in her serum. The husband and two of the children were Group O and Rh+. The first four donors used after the sixth pregnancy were all Group O and Rh+. Their cells were agglutinated by the patient's serum at 37°C. after 1 hour's incubation. The cells of the Rh-donors used subsequently were not agglutinated by the patient's serum.

COMMENT

In Cases 1, 2 and 3, the reactions occurred following the use of Rh+ blood for patients who were lacking the Rh factor and had been immunized by previous transfusions, probably from Rh+ donors. However, the anti-Rh agglutinin was not demonstrable by in-vitro tests on the serums of these patients immediately after the reactions occurred, when it presumably might have been absent because of having been absorbed out by the donor's Rh+ cells or, in one case, even at a later time when it might have reaccumulated. It may be assumed that the titer of this antibody was relatively low in these patients, not only because of the failure to demonstrate agglutination but because the transfusion reactions were not very severe, and especially because donors' cells were still circulating, unagglutinated, in the recipients' blood streams twenty-four hours after the transfusions. This caused some confusion in reading the Rh tests on the patients' bloods at this time, since there were some clumps of cells, suggesting an Rh+ result. But the majority of the cells showed no agglutination with the anti-Rh testing serum, indicating a mixture of a small number of Rh+ cells with a larger amount of Rh- blood. Tests a week or more after the reaction showed only Rh- blood in each recipient, the donor's incompatible Rh+ cells having been destroyed. One or more transfusions from known Rh- donors were given, without untoward reactions. In Case 3, testing for M and N factors confirmed the fact that the

first blood sample after the transfusion reaction contained mixed blood.

Case 4, in which the patient had congenital hemolytic jaundice, is of interest because of the occurrence of five transfusion reactions when the bloods of donors later proved to carry the Rh factor were used. The first transfusion from the patient's husband, whose blood was Rh+, stimulated the isoimmunization that led to the later reactions. The only transfusion other than the first that was tolerated without untoward effect was the third, from a donor later shown to be Rh-. The anti-Rh agglutinin could not have been a strong one, for in three separate tests it was not demonstrable in vitro and the patient survived five injections of incompatible blood, totaling 1625 cc., in four months.

Case 5 is baffling because the patient, a child suffering from chronic nephritis with the nephrotic syndrome, showed an anti-Rh agglutinin without ever having received a transfusion, according to the history, and careful investigation failed to reveal any discrepancy in this story. It raises the interesting possibility of a naturally occurring anti-Rh agglutinin in some persons who lack the Rh factor. Possibly the nephrotic state had some bearing on this, for in Wiener's⁷ Case 8, the patient was an Rh- child with nephrosis who failed to show an increase in the red-cell count even with the first few transfusions of Rh+ blood. This suggests the presence in this patient of an anti-Rh agglutinin that only in subsequent transfusions became sufficiently strong to produce a true transfusion reaction.

The next four patients (Cases 6, 7, 8 and 9) developed anti-Rh agglutinins not as the result of previous transfusion with Rh+ blood but through isoimmunization by the fetus. In each case the father and the children were Rh+, whereas the mother's blood lacked this factor. Although in each family the first child had shown no evidences of erythroblastosis foetalis, — and this is the usual finding, — the second pregnancy had resulted in the birth of an infant with this condition. Levine et al.⁹ have postulated that the first infant usually escapes because one or more pregnancies involving an Rh+ offspring may be necessary to induce a sufficient degree of isoimmunization in the Rh- mother to harm the fetus and produce the symptoms of the disease. In the 4 cases reported here, the anti-Rh agglutinin was easily demonstrable in tests of the serum and thus explained the severe reactions that followed transfusion with Rh+ blood. The use of Rh- blood was regularly successful.

Isoimmunization through pregnancy rather than through previous transfusion alone seems to pro-

ice a higher, more sustained and easily demonstrable titer of anti-Rh agglutinin.* Certainly, reactions even with the first incompatible transfusion in such women tend to be severer or even fatal, whereas in Cases 1, 2, 3 and 4 several incompatible transfusions were given without the development of kidney insufficiency or serious hemolysis.

Case 10 illustrates the damage that may result when an Rh- woman married to an Rh+ man develops isoimmunization as the result of transfusions of Rh+ blood. This patient had eight transfusions, most of them, presumably, from

This, however, was the stimulus to isoimmunization. The next infant developed erythroblastosis foetalis and succumbed shortly after birth. Further transfusion with Rh+ blood resulted in serious reactions, with kidney insufficiency and eventual death.

SUMMARY

Brief case histories of 10 patients who suffered hemolytic transfusion reactions are presented (Table 1). In every case, the recipient received compatible blood according to grouping and cross-matching by the ordinary methods. Later inves-

TABLE 1. *Summary of Data.*†

SE No.	SEX	AGE yr.	DIAGNOSIS	MEANS OF ISOIMMUNIZATION	RESULTS OF ANTI RH TESTS
1	M	45	Aplastic anemia	Repeated transfusions	Immediately after reaction, negative 11 days later slight trace
2	M	30	Bleeding (duodenal ulcer)	Repeated transfusions	Immediately after reaction negative, 11 days later negative
3	F	12	Bleeding (intestinal polyps)	Repeated transfusions	Immediately after reaction negative, 2 weeks later, trace
4	F	54	Congenital hemolytic jaundice	Repeated transfusions	Two days 11 days 11 months after reaction, all negative
5	M	5	Chronic nephritis with ascites and edema	Not known (possibly spontaneous isoagglutinin)	At 2 tests, trace
6, 7, 8, 9	F	22-34	Pregnancy with post partum bleeding	Pregnancy with Rh+ fetus	Trace to moderate reactions
10	F	19	Pregnancy following thoracoplasty and hemorrhage	Repeated transfusions, possibly pregnancy with Rh+ fetus	No tests done
11	F	40	Pregnancy with post partum bleeding	Repeated transfusions, possibly pregnancy with Rh+ fetus	Strong titer after fourth reaction

†In every case except Case 5 (where an incompatible transfusion was avoided) tests for the Rh factor showed the recipient to be Rh- and the donor's blood producing the reaction to be Rh+, mixed reactions were found in Cases 1, 2 and 3, as described in the case reports.

th+ individuals. The last two were followed by hemolytic reactions. Her first pregnancy resulted in a baby with severe hydrops due to erythroblastosis foetalis. This is a rare if not unique occurrence. It suggests that the mother carried a high titer of anti-Rh agglutinin from early in pregnancy, possibly increased by the presence of the Rh+ fetus, and that this soluble antibody produced severe damage in the infant. This enforces the urgent need for using only Rh- blood for transfusions, especially repeated ones, in Rh- patients, for the protection both of the recipient and—in women—of the potential offspring.

Case 11 offers even more fertile ground for speculation concerning the damage to an Rh- woman and her future children that may result from a transfusion with Rh+ blood. This mother had given birth to four Rh+ children with no stigmas of erythroblastosis foetalis. Thus there was no evidence of isoimmunization, especially since after her fifth pregnancy she was able to tolerate transfusion of Rh+ blood without reaction.

*Levine in personal communications has mentioned repeated observations affirming the belief that better immunizing opportunities are afforded pregnancy than by repeated transfusions.

tigation disclosed that the incompatibility involved the Rh factor. Each recipient was Rh-, and through the development of isoimmune bodies to the Rh factor suffered a hemolytic reaction when Rh+ blood was administered.

Isoimmunization occurred in some patients as the result of previous transfusions with Rh+ blood; in others, as the result of a pregnancy involving a fetus having Rh+ blood cells. In still another patient, an anti-Rh agglutinin of natural origin seemed to be present.

Mixtures of recipient's Rh- cells and donor's Rh+ cells were observed in the blood of 3 patients shortly after hemolytic transfusion reactions had occurred. This necessitated care in interpretation of the test for Rh+ cell agglutination. In 2 cases, women of childbearing age developed isoimmunization to the Rh factor through the use of Rh+ blood for transfusions, and in both these cases, this seemed to have been the direct cause of the birth of an infant with severe erythroblastosis foetalis in a subsequent pregnancy.

Following the hemolytic reaction, the use of Rh- blood for subsequent transfusions in each patient resulted in no further difficulties.

CONCLUSIONS

Patients who are likely to have repeated transfusions should be typed for the Rh factor, to avoid immunizing Rh- persons by the use of Rh+ blood. This is especially important in women of childbearing age, to avoid the possibility of harming an Rh+ fetus at a later pregnancy.

Women who may require transfusion during or after pregnancy should be typed for the Rh factor and, if Rh-, receive only similar blood. This is especially important if the obstetrical history suggests the birth of an infant with erythroblastosis foetalis. In the latter event the husband is a dangerous donor.

The modified compatibility test of Levine (incubation of the mixture of donor's cells and patient's serum before examination for agglutination) occasionally reveals the presence of the anti-Rh agglutinin in the recipient's serum. If negative, however, it is not a guarantee that a hemolytic reaction will not occur.

Rh- donors should be listed and be available for transfusion of Rh- patients, or those untyped recipients whose history suggests the possibility of transfusion reactions.

Laboratories should be equipped, at least in the larger medical centers, to carry out typings for the Rh factor, thus helping to procure Rh- donors, to detect anti-Rh agglutinins and to study, and so help to prevent, transfusion reactions.

THE TREATMENT OF CANCER OF THE PROSTATE WITH CASTRATION AND THE ADMINISTRATION OF ESTROGEN*

A Preliminary Report

RICHARD CHUTE, M.D.,† AND LIEUT. ARTHUR T. WILLETTTS (MC), U.S.N.R.‡

BOSTON

IN THE spring of 1941, Huggins and his co-workers^{1,2} reported a series of cases of carcinoma of the prostate with demonstrable metastases or local extension, the majority of which had been greatly benefited both subjectively and objectively by reducing the physiologic action of the androgens in the body. This had been accomplished either by reducing their production by surgical castration, or by biochemically inactivating or neutralizing the existing androgens by the administration of estrogen or by a combination of the two. In view of the obvious importance of this work, a brief explanation of the principles involved seems indicated.

Huggins attacked the problem of carcinoma of the prostate in various ways, one of which was by investigating its connection with so-called "acid" phosphatase. This enzyme is thus named because it manifests an optimum activity at about pH 5.0, as distinguished from the better-known alkaline phosphatase, whose optimum activity occurs at about pH 9.3 and which is associated with osteoblastic activity in the bones. Before puberty, acid phosphatase is present in prostatic tissue in only small amounts, but after puberty it is found in large amounts in the normal prostate, which is the chief source of acid phosphatase in the body. Furthermore, acid phosphatase is also present in large amounts not only in prostatic carcinoma tissue but also in the tissue of the metastases to bone of this disease. It is also known that acid phosphatase is present in the serum of patients with metastases from carcinoma of the prostate in a far greater concentration than in the serum of normal men or men with prostatic cancer but without metastases.³ This is thought to be due to neoplastic invasion of the lymph or blood channels with escape of the enzyme into the circulating fluids. Thus it is supposed that an elevated serum acid phosphatase signifies cancer of the prostate with metastases, and that a rising level of serum acid phosphatase indicates an increase of metastatic disease, with an unfavorable prognosis. These facts suggested to Huggins the probability that many cases of prostatic carcinoma represent a ma-

lignant overgrowth of adult prostatic epithelial cells, and that therefore the same factors that inhibit the growth of adult prostatic epithelial cells may also inhibit the growth of prostatic carcinoma cells. He knew that prepuberal castration usually prevents the development of the prostate, and he also knew from the clinical reports in the 1890's of White⁴ and of Cabot,⁵ and from his own experimental work,⁶ that surgical castration causes atrophy of adult prostatic epithelial cells. Furthermore, he knew from his own work⁷ and that of others^{8,9} that the administration of estrogen did the same thing. Therefore, he tried surgical castration or estrogen administration, or a combination of the two, on more than 20 cases of carcinoma of the prostate, using the behavior of serum acid phosphatase, in those cases where it was elevated owing to metastases, as one of the yardsticks of the amount of activity of the prostatic carcinoma cells and of their response to any inhibiting influence. He found that this type of therapy reduced an elevated serum acid phosphatase practically to normal, and therefore presumably greatly reduced the activity of the prostatic carcinoma cells. Another evidence of reduction of this activity, and a result obviously of the utmost clinical significance, was the occurrence of a great diminution in the size and induration of the carcinomatous prostate itself. In addition, metastatic pains were greatly relieved, and the general condition of the patient improved markedly.

These favorable results reported by Huggins in about 80 per cent of his series of more than 20 consecutive patients, some of whom had been followed for more than two years, were so promising in the treatment of this particularly difficult and distressing disease that we were prompted to try this type of treatment at the Massachusetts General Hospital. This paper deals with the results obtained in 37 patients with carcinoma of the prostate treated from July, 1941, to July, 1942. Although at the time of writing nearly 50 cases have been so treated, the follow-up period on the later cases has been so short that it seems more suitable to present the results only in the 37 cases treated during the first year. A year is, of course, too short a time in which to be able to appraise the final value of the treatment, but since

our preliminary results have been so favorable, and since the successful results in some of Huggins's cases have lasted at least three years, it seems proper to present a preliminary report at this time.

As a preamble, it should be emphasized that we do not recommend this type of treatment except as an adjunct to surgery, in the treatment of those early cases of carcinoma of the prostate that permit entire removal surgically and that are without demonstrable metastases. In such cases, we carry out complete extirpation of the gland by radical perineal prostatectomy, although in addition we perform orchidectomy as a deterrent to the growth of any prostatic cancer cells that may possibly have escaped removal. Unfortunately, however, such early cases are not common, and the vast majority of cases of carcinoma of the prostate that present themselves are not only locally inoperable but frequently have metastases demonstrable by x-rays.

All but 4 of our 37 cases were definitely proved to be carcinoma of the prostate by microscopic examination of tissue, and there was convincing clinical evidence in these 4, as 2 patients had hard prostates with an x-ray picture of typical bone metastases, and the other 2 showed obstruction to urination by enlarged, hard and irregular prostates that became much smaller and softer within a few months after castration. We have recently been using the biopsy needle, as described by Silverman,¹⁰ through the perineum, with some little success in establishing the diagnosis of carcinoma of the prostate in debatable cases, and in the future there should be no case in which tissue is not obtained for pathologic examination. Eight of the 37 cases were treated simply by the administration of the potent synthetic estrogen, diethylstilbestrol, or the closely related diethylstilbestrol dipropionate—both hereinafter referred to simply as stilbestrol.

In selecting an estrogenic substance, we chose two cases were treated with castration alone, while the remaining 27 cases (73 per cent) were treated with a combination of castration and stilbestrol. the synthetic estrogen, stilbestrol,* partly because others had reported success with its use, partly because it was less expensive than the natural estrogens, and partly because in addition to being highly effective when injected, it is also much more potent when taken by mouth than an equal amount of any oral preparation of a natural estrogen, it being considered that only twice the dose must be taken orally to produce the same effect as by injection. At first, we employed diethylstilbestrol or diethylstilbestrol dipropionate in the treatment of our cases, but since we were unable

to detect any significant difference in effect between the two, we used the dipropionate almost entirely in the last three quarters of the series.

Our original plan had been to use castration alone, unless this was refused by the patient, but we then found that stilbestrol increased the castration effect markedly, giving a much more rapid and marked effect than castration alone. For instance, 2 of our early patients, two months and three months respectively after castration, had improved markedly in general condition, but had not shown much reduction in the size of their prostates. However, after ten days of intensive therapy with injections of stilbestrol their glands became markedly smaller and softer. In view of this we used a combination of castration and stilbestrol in all but the early cases. We also found that the results from stilbestrol without castration were in every way the equal of those from stilbestrol with castration. However, the effect of castration, even if slow, is permanent, whereas if stilbestrol alone is used the effect lasts only during its administration and symptoms soon return if it is discontinued, and therefore patients have to be carried on a small oral maintenance dose indefinitely; this we have done in some cases for many months without any obvious deleterious effect.

In evaluating the worth of any new form of therapy, it must first be shown that the therapy is beneficial, and secondly that the beneficial effects outweigh any unfavorable ones. In dealing with cases of incurable carcinoma of the prostate the results that are desirable to achieve are relief of pain, improvement in the patient's general condition and regression of the growth of the gland, with improvement in voiding ability. In almost all our cases the results along each of these lines were quite satisfactory.

Perhaps the most immediate and striking result of treatment was the rapid relief from the severe pain due to metastases. In 12 (32 per cent) of our cases, all but 1 of which had metastases to the bones of the pelvis or spine demonstrable by x-ray, pain was a prominent feature. In 11 of these the pain was quickly and almost completely relieved—in 1 case by castration alone, in 4 cases by stilbestrol alone, and in 6 by castration and stilbestrol. Sometimes the rapidity of the relief was astonishing. One patient got complete relief within twenty-four hours after castration, another experienced the same thing within three days, while the severe pains of a third vanished in five days after the injection of a total of 10 mg. of stilbestrol. A man of eighty-four, who had been bedridden on account of agonizing pain in the spine and legs, got up for the first time in four months after 100 mg. of stilbestrol had been injected in ten days. A patient

*The diethylstilbestrol and diethylstilbestrol dipropionate were kindly supplied by the Department of Medical Research, Winthrop Chemical Company, New York City.

with metastases to the spine and pelvis had a pathologic fracture of the first lumbar vertebra that kept him miserable and in constant pain. After castration followed by 135 mg of stilbestrol, his pain, which was rather slow to subside, had gone completely in seventeen days. When he was seen one month later he had discarded his brace which he had been

The effect of the treatment on the prostate itself was quite marked, and the gland was observed to become both smaller and softer in all but 6 cases. In 4 of the latter, the follow up time was too short for shrinkage and softening to have taken place, although their later occurrence is possible and even quite probable. However in the other 2 cases

FIGURE 1 Cystoproctograms Showing Reduction in Size of the Prostate after Treatment

- A—Before treatment the prostate was somewhat enlarged and had biopsy shown adenocarcinoma. Voiding was difficult and the residual urine was 180 cc. Metastases were present in the spine and pelvic bones. The acid phosphatase was 448 Gutman units and the alkaline phosphatase 23 Bodansky units per 100 cc.
- B—Nineteen days after orchiectomy and after the injection of 115 mg of diethylstilbestrol the prostate felt much softer as well as smaller. Voiding was normal with a negligible residual urine. The acid phosphatase was 42 Gutman units and the alkaline phosphatase 33.3 Bodansky units per 100 cc.

wearing for the pathologic fracture, had a good appetite and had gained weight, and said he was a different man. Seven months later the improvement had been maintained. All but 3 of these 11 patients have been seen recently and have continued to be free from pain.

After the relief of pain, the next most noticeable effect of this treatment was the almost universal improvement in appetite, weight, strength and feeling of well being, which occurred in all but 3 cases. Before therapy many patients were miserable and cachectic, and had disturbances of gastric function ranging from anorexia to nausea, often with considerable loss of weight. Within a few days they began to feel better and their appetites improved with such complete regularity that the change seemed like a physiologic response. As a result there was a noticeable gain in weight

in a reasonable trial with castration and stilbestrol. It failed to cause shrinkage and softening so that they must be considered as having definitely failed to react to the treatment. In 4 cases of the series the prostate virtually disappeared, leaving only a small soft remnant. The degree of softening, although it was marked in most cases, varied, and there were a few glands which, while definitely softer, remained fairly firm during the period of observation.

To convince those who might be skeptical of such remarkable diminutions in size, especially when determined by rectal palpation which is admittedly subject to the individual variations of examiners, the prostate was measured both before and after treatment in a number of cases by the method of Pearson and Wilson¹¹ and the reduction was demonstrated graphically by x-ray

Having discovered how markedly and rapidly stilbestrol reinforced and augmented the castration effect and reduced the size of the prostate, we car-

unable to void satisfactorily after receiving 100 mg. of stilbestrol in ten days or two weeks, it seemed a needless extravagance to prolong his hospital stay

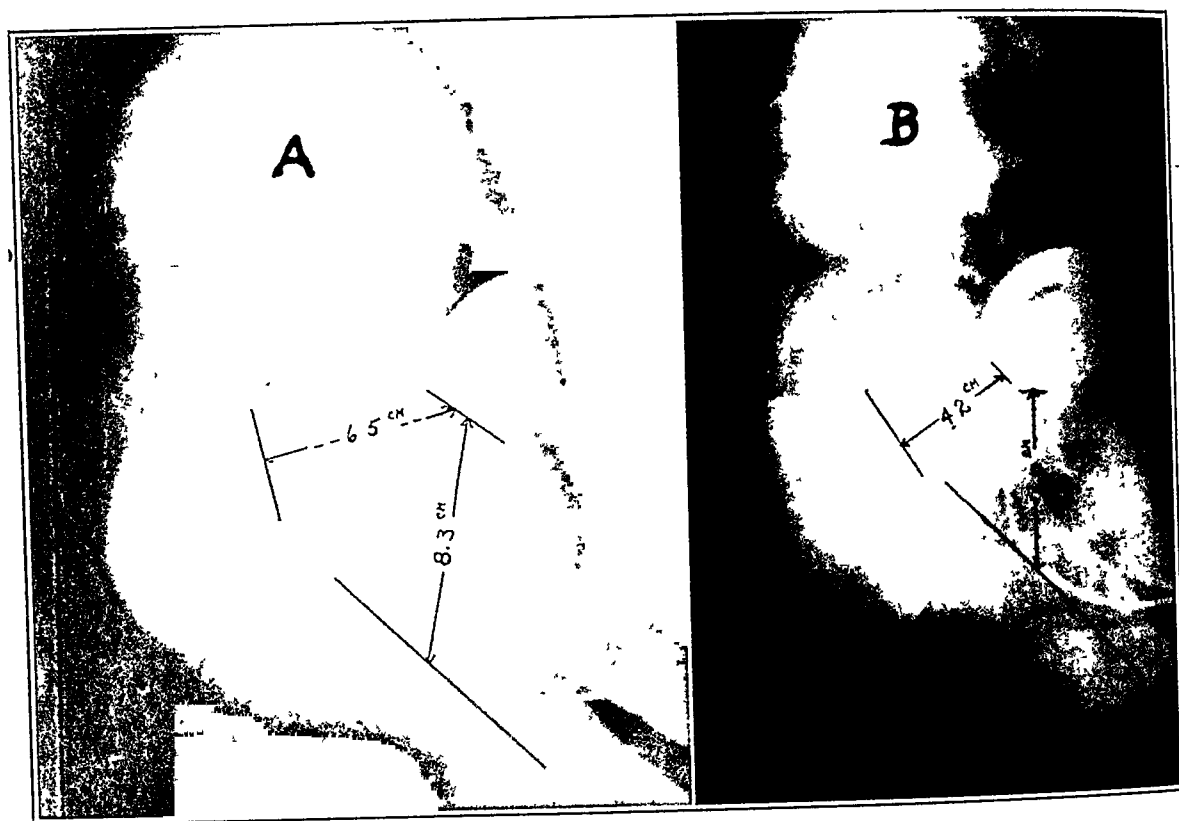

FIGURE 2. Cystopneumograms Showing Reduction in Size of the Prostate after Treatment.

A—Before treatment, the prostate was greatly enlarged and stony hard; biopsy showed adenocarcinoma. Voiding was difficult, and there was a residual urine of 500 cc. Metastases were present in the pelvic bones and spine, with a pathologic fracture of the first lumbar vertebra. The patient could not move about in bed without agony. The acid phosphatase was 39.5 Gutman units, and the alkaline phosphatase 13.5 Bodansky units per 100 cc.

B—Twenty-one days after orchidectomy and after the injection of 135 mg. of diethylstilbestrol, voiding was normal, with no residual urine. The prostate was not only much smaller but markedly softer and no longer felt like carcinoma. The pain was greatly improved, and the patient was up out of bed. The acid phosphatase was 7.5 Gutman units, and the alkaline phosphatase 32.6 Bodansky units per 100 cc.

ried out the following procedure in 13 cases of inoperable carcinoma with retention of urine. The patient was put on constant catheter drainage, and after preliminary laboratory and x-ray studies bilateral surgical castration was carried out by the intracapsular technic. Shortly after this, a series of injections of stilbestrol was started, 10 mg. being injected intramuscularly every day for five to ten days. By that time favorable effects had usually commenced, including relief of pain, shrinkage in the size of the prostate and improvement in ability to urinate. This treatment was so effective that 9 of these 13 patients who had been admitted with moderate or marked inability to urinate were enabled to void freely, did not have much residual urine and therefore never had to undergo a prostatic operation. However, if a patient was still

for further injection therapy, and he was subjected to transurethral resection.

Determinations of the acid phosphatase were made on 20 patients before and after castration. Our findings confirmed those of Huggins.^{1,2} In every case where the acid phosphatase was definitely above normal (7 cases), the level fell very rapidly following castration, and was still further reduced following intensive injection therapy with stilbestrol. Our findings also agreed in general with those of Robinson, Gutman and Gutman³ and those of Huggins in that 5 of the 7 cases with elevated acid phosphatase had roentgenologically demonstrable metastases to bone. However, the metastases did not necessarily cause an elevation, as there were cases with metastases demonstrable by x-ray in which the acid phosphatase level

was normal. Thus it would appear that elevation of the acid phosphatase, if present, strongly indicates metastases, but that a normal value for acid phosphatase does not necessarily rule them out. There seemed to be no definite correlation between the elevation of the acid phosphatase and pain. Six of the 12 cases where pain was a prominent feature had determinations of the acid phosphatase before treatment, and this was elevated in only 1. In this case, following castration and estrogenic therapy, the level came down to nearly normal within one week—ten days before the pain was fully relieved. Furthermore, the patient who had the highest acid phosphatase level of any of our series (44.8 Gutman units per 100 cc.), with widespread metastases to the pelvis and spine, had absolutely no pain. His acid phosphatase decreased to 10 Gutman units within six days after castration. The original level had no prognostic value regarding the probability of the success of the treatment, as favorable results were obtained in cases with both normal and elevated values. The level in the 1 case that was apparently not benefited at all was approximately normal, and was not reduced by the treatment.

Estimations of the alkaline phosphatase were made before and after castration in 22 cases, elevated values being found before operation in 10 of these. In 8 of the 10, bony metastases were demonstrable by x-ray, 1 had extensive Paget's disease, and in 1 case the x-ray films were equivocal. Our experience agreed with that of Huggins in that there was usually a rise in the alkaline phosphatase shortly following castration, either with or without stilbestrol.

Measurements of the 17-ketosteroids were made before and after castration in 23 cases. As was to be expected, in most cases they decreased after orchidectomy. In several cases where they did not, the acid phosphatase had decreased and the patients were doing well clinically. Conversely, 2 patients who did poorly (1 of them died) had 17-ketosteroids that became low after castration and remained low for several months afterward, during which time their metastases were increasing and their general condition was worsening. Therefore our general impression is that the measurement of the 17-ketosteroids does not give information of great value in the management of cases of carcinoma of the prostate.

Despite the almost universal relief of the pain of metastases by this treatment, we have not yet been able to detect any roentgenologic evidence of favorable effects on bony metastases, such as inactivation or regression, as have been described by some authors. In 5 cases followed for more than six months (4 of which received castration and stil-

bestrol therapy, and 1 stilbestrol alone), x-ray films have shown the bony metastases to be apparently progressing as usual. A longer follow-up period is needed for us to come to any decision of value.

Of the 37 patients in the series, only 1 was apparently not benefited in any way by this treatment. Despite the fact that he had had castration followed by large amounts of stilbestrol, both by injection and orally, he experienced no relief from his moderate amount of back pain, very little reduction in the size or induration of the prostate and absolutely no improvement in his general condition, which deteriorated progressively. This case was peculiar in that, despite very extensive metastases to the spine, liver and other viscera found at autopsy, the acid phosphatase before any treatment was given was only 4.6 Gutman units per 100 cc.—essentially normal. Furthermore the level was not reduced by castration and stilbestrol therapy. Two days before death, when the patient had been without stilbestrol for twelve days, the acid phosphatase rose to 14.6 Gutman units. That this was a case of carcinoma of the prostate there is absolutely no doubt, as the clinical findings were those of that disease, and the microscopic sections were thus diagnosed by several pathologists.

In addition to the case just described 2 other patients died. In 1 case, with extensive bony metastases, the progress of the disease was halted for six months by castration and stilbestrol. After that time, however, despite the administration of stilbestrol, and although the prostate did not grow, the general condition became worse, and the patient died about a year after castration in a state of profound anemia and weakness. The third patient to die was killed in an automobile accident two weeks following castration, so that sufficient time had not elapsed to evaluate the effect of treatment. Thus out of the 37 patients seen in one year, only 3 died, 2 of their disease and the third from an accident. Of the remaining 34, all but 5 have been seen fairly recently, and all are getting along well; they are in good general condition and have no pain, and none of them look as though they were going to die for a long time.

When it comes to a consideration of the unfavorable effects of castration, it must be said that libido and power of erection never reappeared after orchidectomy in the vast majority of cases. However, to blame this entirely on castration is perhaps not fair, since many of these sick, elderly men had not been sexually active for a long time before castration. No other harmful effects of castration were noted on either mind or body.

To lessen the likelihood of mental distress arising from the feeling of patients that by castration they had been deprived of their manhood, bilat-

eral orchidectomy was in most cases performed by a special technic, which we have called "intracapsular orchidectomy." We began using this technic more than a year ago and have now applied it to nearly 40 cases, having done all our orchidectomies in this manner for the last nine months. After the testis has been exposed surgically, a generous incision is made in the tunica albuginea, and the soft, stringy, tan-colored testicular substance is easily separated with gauze dissection from the inside of the tunica down to the mediastinum. Here the blood vessels, which form a sort of pedicle, are clamped and ligated en masse and the testicular substance is cut away. The incision in the tunica is then sutured. In this way the functioning substance of the testis is removed, but there remain the spermatic cord, the epididymis and the oval mass formed by the sutured tunica albuginea, and the patient is not left with an empty and shrunken scrotum as is the case following the usual type of bilateral orchidectomy. Physical examination after this procedure usually gives the impression that the testes are present although very small. On casual examination the patient finds what appear to be small but normal testes. As a result, although he knows that the essential part of the testes has been removed, he does not feel that he has been completely castrated, as he is sure to feel with an absolutely empty scrotum. This may seem to be a minor point, but it may be of considerable psychological importance in the avoidance of depression in morbidly introspective patients.

As to the unfavorable effects of stilbestrol therapy, there were several, but none of them were very serious. Again, as after castration, the vast majority of those taking the drug lost their libido and power of erection. Also, all those taking stilbestrol, especially those given small oral maintenance doses over a period of weeks or months, developed tenderness, hypertrophy and sometimes pigmentation of the nipples, and frequently some hypertrophy of the whole breast. This was usually not too bothersome; it could be lessened by cutting down the dose, and soon disappeared when the drug was discontinued. Another almost universal effect was that the testes, if present, became definitely smaller. A number of patients while receiving intensive stilbestrol therapy developed edema of the ankles and lower legs, which disappeared when the dose was decreased. A very few also complained of cramps in the legs during intensive injection therapy. Surprisingly few complained of anorexia or nausea, although this occurred in scattered cases, necessitating the temporary discontinuance of the drug or a reduction of the dose. No other unfavorable effects were noted. Therefore, in view of our experience we favor

supplementing orchidectomy with stilbestrol therapy for some weeks or even months thereafter.

As regards the advisability of intensive or prolonged administration of stilbestrol, there have been reports in the literature, based largely on experimentation with small animals, suggesting that such administration might be dangerous. Since it has been shown that stilbestrol is normally detoxified in the liver, attention has been focused on this organ as the most likely to show toxic changes, and huge amounts of stilbestrol—sometimes several thousand times the physiologic estrinizing dose—have been administered to experimental animals in efforts to answer this question. Although not unanimous, the trend of recent opinion is that even very large doses of stilbestrol are relatively harmless to the liver. The harmful effects that have been reported in laboratory animals following administration of tremendous doses include anemia and neutropenia, changes in the pituitary and adrenal glands, and the occurrence of pituitary, mammary or testicular tumors in cancer-strain rats and mice. These changes, however, have been mostly produced by the administration of huge amounts of stilbestrol—hundreds of times the physiologic dose given to man—and recent papers by Grauer and Nugent,¹² Morrell and Hart¹³ and Russell and his co-workers¹⁴ tend to substantiate the growing clinical opinion that, in the doses commonly given to man, stilbestrol does not have harmful effects. Certainly no dangerous or harmful effects were noted in any of our cases. One of our patients who died with widespread metastases to bone and viscera showed absolutely no evidence of toxic liver damage, although in addition to castration he had received 100 mg. of stilbestrol intramuscularly and 200 mg. orally during the six weeks preceding death.

At the present time the following procedure is used in cases of inoperable carcinoma of the prostate. If the patient has much retention of urine, he is put on constant catheter drainage. After preliminary laboratory and x-ray studies, bilateral orchidectomy is performed by the intracapsular technic. In cases with much retention of urine, although we know that by using intensive stilbestrol therapy in addition to castration we can probably in ten days or so shrink the prostate enough so that the patient can void and empty the bladder much better, we now consider this an unnecessary and extravagant prolongation of the hospital stay, and perform transurethral resection at the time of the orchidectomy or shortly thereafter. While in the hospital, the patient receives an intramuscular injection of 10 mg. of stilbestrol every day for five to ten days, if tolerated, to give the endocrine process acting on the pros-

tate an additional impetus beyond that conferred by castration alone. When the patient goes home he is put on a dosage of 1 mg. of oral stilbestrol two or three times a day for two months.

In view of the experiences and results described, we believe that this type of therapy gives a great deal of promise in the treatment of inoperable carcinoma of the prostate.

SUMMARY

Reducing the action of androgens in the body, either by surgical castration or by biochemical neutralization through the administration of the synthetic estrogen, stilbestrol, or a combination of the two, was used in treating 37 cases of inoperable carcinoma of the prostate during the period July, 1941–July, 1942.

Two cases were treated with castration alone and 8 cases by stilbestrol alone. The effect of castration was accelerated by the addition of stilbestrol therapy, and this combination was used in 27 cases (73 per cent). The results of stilbestrol therapy alone were in every way the equal of those of castration and stilbestrol, but the effect of stilbestrol alone lasted only during its administration.

The general results were very satisfactory, and only 1 patient seemed to receive no benefit at all from the treatment. Three patients died during the year.

The beneficial effects included rapid, effective and lasting relief from the pain of metastases, improvement in appetite, weight and strength and a feeling of well-being, and reduction and softening of the prostate.

In 9 of 13 cases with inability to urinate and retention, treated with orchidectomy and stilbestrol, the size of the obstructing prostate was so reduced that the ability to void returned.

Determinations of the acid phosphatase showed that when the level was above normal preoperatively it fell rapidly after castration, and was still further reduced by stilbestrol therapy.

The alkaline phosphatase usually rose shortly following castration, with or without stilbestrol.

The 17-ketosteroids were lowered in most cases after orchidectomy. The level seemed to have no relation to the course or progress of the disease.

In 5 patients with bony metastases demonstrable by x-ray who were followed for more than six months, the metastases were apparently progressing as usual.

After castration, libido and power of erection disappeared in most cases, but there were no other harmful effects.

No dangerous or harmful effects were noted from stilbestrol therapy, either from intensive injection therapy or from long-continued oral therapy. There were, however, minor unpleasant effects. All these soon disappeared if the drug was discontinued or the dose decreased.

A new technic of cosmetic intracapsular orchidectomy is described.

THE CARE OF PATIENTS REQUIRING THYROIDECTOMY

OLIVER COPE, M.D.,* AND CLAUDE E. WELCH, M.D.†

BOSTON

THE Massachusetts General Hospital, under the supervision of the Thyroid Clinic, trains interns and residents in the care of patients with disease of the thyroid gland. Written instructions for the guidance of the House Staff maintains continuity of the standard of care and teaching. The directions dealing with patients to be treated by operation are given below, in the hope that they may prove useful to other hospitals and physicians.

To keep the operative mortality of patients with goiter, and especially with hyperthyroidism, at the lowest possible level, the following recommendations should be kept in mind.

CLASSIFICATION

On both the medical and surgical services an estimate of the operative risk of each patient should be made. Whether hyperthyroidism is present must first be settled — masked hyperthyroidism in older people is easily overlooked. It also should be appreciated that an elderly patient with an obstructing goiter without thyrotoxicosis may present just as great an operative risk as a younger patient with thyrotoxicosis.

Patients are grouped in three classes according to operative risk:

Class A — Good Risks: Patients with uncomplicated nontoxic goiter, and young patients with toxic goiter of mild intensity.

Class B — Medium Risks: Patients with uncomplicated, moderately severe toxic goiter, with obstructing or mediastinal goiter and with cancer of the thyroid gland.

Class C — Poor Risks: Patients with thyrotoxicosis who present any of the following criteria of inability to stand operation well; extreme intoxication indicated by high basal metabolic rate, severe symptoms or crisis status; a rising basal metabolic rate; poor or absent iodine response; failure of the pulse rate to drop on bed rest and iodination (that is, lack of cardiac reserve); the presence of cardiac complications, such as insufficiency, fibrillation, hypertension and a valvular lesion, or a history of paroxysmal fibrillation or tachycardia; a poor nutritional state, including inability to gain weight in the

hospital; an active infection; a psychotic state; and old age.

The last class also includes patients in the older age groups with severe obstructive symptoms without thyrotoxicosis.

PREOPERATIVE CARE

The following points apply in some degree to all patients who are to have a thyroidectomy. Their fulfillment is mandatory in Class C patients; judgment must be used in their application to Class A or B patients.

- (1) Patients must be fully iodinated and have been on bed rest long enough to build up a maximum cardiac reserve.
- (2) Patients must be free from active infection, throat or other. Sulfonamide therapy should be instituted only after due consideration of the concept that toxic reactions to sulfonamide drugs are peculiarly undesirable in thyrotoxic patients who are already suffering from a nutritional handicap and an impending hepatic insufficiency. Sulfonamides are indicated in severe, acute infections that threaten to produce a thyroid storm, and in certain persistent subacute infections. A long interval of hospitalization should intervene between drug therapy and operation, particularly if a toxic reaction has occurred. Rarely should sulfonamides be used as an immediate preoperative preparation. Local use of sulfonamide powder in the wound at operation may be warranted, but in general if infection exists in the neck, thyroidectomy must be postponed.
- (3) Preoperative preparation should be long enough to ensure a good nutritional reserve, as well as to dissipate any deficiency. Measures must be taken to build up stores of vitamins, protein and liver glycogen. An increase in all foodstuffs, proportionate to the elevation of the metabolic rate, is required.
- (4) Nembutal, luminal and Amytal are advised for sleeplessness. Paraldehyde may be used, but occasional excitement ensues. Bromides, as well as luminal in small doses, are useful for restlessness. Codeine is permissible for cough, and with aspirin for pain. Morphine, Pantopon and Dilaudid are reserved for crisis and preanesthetic preparation. Chloral hydrate is

*Assistant professor of surgery, Harvard Medical School; associate visiting surgeon, Massachusetts General Hospital.

†Assistant in surgery, Harvard Medical School; assistant surgeon, Massachusetts General Hospital.

contraindicated in the presence of cardiac difficulty and is therefore rarely useful in thyrotoxicosis. Atropine should be used with caution in view of its vagal inhibitory effect.

- (5) Throat consultation is required to exclude contraindications to intratracheal anesthesia (ulcers or inflammation), as well as to determine any pre-existing cord palsy. If the resident and anesthetist are satisfied by inspection that the larynx is normal, consultation by a laryngologist may be omitted in Classes A and B.
- (6) Chest roentgenograms to determine the presence of intrathoracic goiter and anteroposterior and lateral plates of the neck to check tracheal displacement and narrowing are necessary only if configuration of the palpable goiter is in doubt. Fluoroscopy and a 7 foot plate of heart are required if the cardiac findings are disproportionate to the metabolic rate.
- (7) An electrocardiogram should be taken if the heart findings are not accounted for by the thyrotoxicosis.
- (8) Digitalis and a longer rest period, a minimum of three weeks, are required in patients with congestive failure. Digitalis should also be given to all patients in whom auricular fibrillation persists after iodination and bed rest; it should be discontinued after operation, when the hyperthyroidism has been relieved, to remove its stabilizing effect on the fibrillation. Digitalis is advisable in patients in the older age groups with no failure and with regular rhythm whose cardiac capacity is small or no greater than the load. Such digitalization helps to counterbalance the additional burden of operation.
- (9) Quinidine, pre- and postoperatively, should be considered in cases with a history of paroxysmal fibrillation or tachycardia; it should be given to all cases in Class C except those with active auricular fibrillation. It should be started twenty-four hours before operation and continued until the load on the heart is sufficiently relieved to make fibrillation unlikely, usually twenty-four to thirty-six hours after operation.
- (10) The anesthetist should be consulted regarding the choice of anesthesia and any basal medication to be given on the ward.
- (11) These patients must be operated on early in the morning; the operation must not be postponed except for the patient's own good.

Reassurance of patients with thyrotoxicosis before operation regarding the entire operative pro-

cedure is most important. They should be informed concerning what to expect of the anesthetic, postoperative discomfort, intravenous injections and the oxygen tent. The use of the term "air conditioned tent" producing cool, moist air for sore throat is suggested. If such reassurance is inadequate a preoperative trial of the tent is indicated.

Crisis

The course of hyperthyroidism is subject to exacerbations and remissions. If an exacerbation comes on acutely with severe symptoms, the episode is called a thyroid "crisis" or "storm." To a more rapid pulse rate and pounding heart there may be added a high fever and a physical and emotional instability difficult to control. It is as if the smoldering fire of the thyrotoxicosis had suddenly been fanned to flame. If the storm is progressive, death may occur suddenly. The fever increases the metabolic rate, nutritional deficiency develops rapidly, and it is believed by some that hepatic insufficiency is the cause of death.

A crisis may occur at any time during the disease. It may be induced by an acute infection or severe emotional strain before operation. The commonest causes are operation itself and the postoperative complications. Until the thyrotoxicosis is relieved, the threat of a storm must be kept in mind. No matter when it occurs, the treatment is symptomatic, except for the administration of iodine. Reassurance and sedation for the instability, ice packs for the fever, an oxygen tent and every effort to maintain nutrition are indicated. The use of iodine should be instituted immediately if it has not been given; it should otherwise be continued. Nothing is gained by increasing the dosage provided that the previous doses have been sufficient to saturate the gland.

OPERATION

Anesthesia

Adequate oxygenation in thyrotoxicosis is the paramount consideration, and a free airway must be maintained no matter which agent is used. Hyperextension of the neck, necessary for good exposure of the thyroid gland, tends to produce laryngeal obstruction. Tracheal constriction is a hazard of the induction of either local or general anesthesia. Tracheal obstruction may occur, and the surgeon should be prepared to open the neck rapidly.

The base line of the patient's reaction to removal to the operating room should be obtained before any anesthetic agent is started. The pulse and blood pressure should be followed at five minute intervals while the patient is being transferred to

the operating table. When general anesthesia (ether) is used, the induction should not be hurried, and it is wise to wait until the patient is stabilized under the anesthesia before starting the operation. Undue emotional reaction caused by being taken to the operating room should disappear under the anesthetic agent. If it does not, the operation should be postponed. The operation should not be begun until one is sure of the patient's condition.

Agents of choice. Local procaine is useful for patients in Class A with a bilateral operation, and in Class C patients in whom preoperatively it is possible to decide that a hemithyroidectomy is advisable. A satisfactory bilateral operation under local anesthesia requires considerable basal anesthesia of barbiturates and opiates; adequate oxygen intake is sometimes hampered during and after operation by such heavy medication and is therefore contraindicated in Class C risks. Adrenalin should not be added to the procaine solution; the thyroid hormone sensitizes the heart to adrenalin, and the likelihood of fibrillation is increased.

A preliminary trial of the medication to be used in the basal anesthesia is sometimes advisable. The best way, however, to judge the dosage of barbiturates and opiates required is to observe the reactions of the patient during the period of administration. The initial medications should be given one and a half to two hours prior to the time of operation, and subsequent doses as needed.

Oxygen, nitrous oxide and ether, given intratracheally, is preferable, and is indicated in Class C. The one contraindication of an intratracheal tube is that it may increase the incidence of laryngeal edema and obstruction. Three measures should be taken to decrease laryngeal edema when an intratracheal tube is used. First, the tube must be inserted under direct vision without trauma; secondly, particular care on the part of the surgeon must be taken to avoid trauma to the trachea and larynx and to avoid distorting the trachea while the tube is in place. Thirdly, patients with preoperative laryngitis requiring an intratracheal tube should have only a hemithyroidectomy, to maintain adequate venous and lymphatic return to at least one side of the larynx.

Permissible agents. Nitrous oxide (70 per cent) and oxygen (30 per cent) may be used as an adjunct to local anesthesia when the airway is unobstructed. Such anesthesia will not permit use of an intratracheal tube.

Agents absolutely contraindicated in thyrotoxicosis. Cyclopropane may induce ventricular fibrillation in patients with thyrotoxicosis. Avertin produces inadequate oxygenation through direct effect on the circulatory system and the respiratory cen-

ter; it also causes liver damage, an effect particularly undesirable in patients with the impending hepatic insufficiency of thyrotoxicosis. The toxic effects of Avertin are similar to those of chloroform and ethyl chloride, and include, besides those above mentioned, damage to the renal tubules and possibly ventricular fibrillation.

Extent of Excision

Thyrotoxicosis is caused by two types of disease process. The rare one is hyperfunctioning adenoma, a form of neoplasia; excision of the adenoma alone is indicated since the rest of the gland is uninvolved and is indeed atrophied from disuse. The common type is the diffuse hyperplasia or its involutional result; the amount of tissue to be excised to relieve the thyrotoxicosis and the amount to be left to maintain normal thyroid hormone production vary with the existing degree of hyperplasia, the involution and the ability of the patient to produce regeneration of the thyroid remnant. In general the remnant should be larger when the tissue is well involuted and the thyrotoxicosis mild. It is wise, when in doubt, to err on the side of too radical an excision.

Stage or divided operations are sometimes indicated. With the means of preparation for operation now available, pole ligations are rarely resorted to. Division of the operation into two parts, subtotally resecting one lateral lobe at a time, is indicated in Class C patients with persistent cardiac insufficiency. If the reaction to the anesthetic and operation is greater than anticipated, stage procedures should be used in less sick patients. A continuous rise in the pulse rate and blood pressure during the course of the operation should serve as a warning. A pulse rate of 160 and a systolic pressure of 40 mm. above the preoperative level should be considered maximal heights before terminating the operation.

The surgeon must use his own judgment during the operation concerning how far to proceed. The object should always be to do as much of the subtotal excision as the patient's condition warrants. At least one week should intervene between operations, but in general the second operation should not be performed until the patient has received the maximum benefit from the first.

POSTOPERATIVE CARE

Supervision

Most important to the successful outcome of a thyroid operation is careful watching during the first two days after operation. It is the time of crisis. The excessive thyroid function has not as yet been decreased and the burden of operation and its attendant excitement have been added to

the already taxed organism. The majority of severe cardiac complications, such as fibrillation, flutter or tachycardia with break in compensation, occur in the eight hours immediately after the patient has left the operating room, not during the operation. Hemorrhage and laryngeal edema may not occur until twenty four hours have passed.

The pulse and blood pressure should be carefully followed. A continued rise suggests anoxemia from laryngeal obstruction.

Stridor must be listened for. If it persists when the patient is awake, it warns of concealed hemorrhage with pressure and beginning laryngeal edema, or bilateral-cord palsy. Both may prove to be rapidly fatal lesions, and immediate return of the patient to the operating room and prompt exploration of the wound and visualization of the larynx are indicated. Either cause of laryngeal obstruction usually demands tracheotomy even though the hemorrhage is relieved.

An oxygen tent immediately is indicated for all Class C risks, and should be continued for at least twenty four hours or longer if reaction to the operation continues. It is advised for Class B patients if there has been an undue rise in pulse or blood pressure during operation, but may be abandoned sooner if the untoward signs subside promptly. Increasing the oxygen tension of the inspired air relieves in part the burden of the circulatory system, already overloaded by the demands of thyroid hormone and operation. Should postoperative infection occur, either in the lung or in the wound, the tent should be reinstituted, since infection causes an additional rise in metabolic rate.

Glucose and salt solution should be given intravenously, slowly, to all Class B and C patients in the first six hours. Glucose must be continued during the first forty-eight hours if drinking by mouth is inadequate on account of pain or nausea. High carbohydrate, protein and vitamin intake should be resumed as quickly as the patient tolerates it.

Iodinization should be resumed as soon as the patient can drink comfortably. Since previous iodination has already saturated the gland, nothing is gained by giving iodine intravenously or by mouth immediately after operation. It is resumed within a few days to replace that which is slowly excreted. If the metabolic rate is below normal within two weeks after operation, iodine may be omitted, otherwise, it should be continued until it is certain that a normal or subnormal metabolic rate has been established.

Special nursing for Class C patients is usually desirable.

Aspirin water and benzoin inhalations are given for throat symptoms. Icecaps may be tried.

Transfusion is ordinarily indicated only when postoperative hemorrhage has occurred. It is rarely a part of the preoperative preparation, and since hemorrhage at operation should not occur with the modern careful technic of thyroidectomy, it is not part of the routine care of patients with thyroid disease.

Postoperative parathyroprival tetany is to be differentiated from hyperventilation tetany by the blood calcium level and the effect of rebreathing. When parathyroid glands are sought and spared, not blindly avoided, at thyroidectomy, postoperative tetany is rare. When at least one parathyroid gland has been seen and not injured, if tetany occurs, it is probably due to hyperventilation. Reassurance is usually adequate therapy. For low-calcium tetany, calcium gluconate or chloride is indicated, by vein or mouth, such tetany must be treated promptly and vigorously to prevent laryngeal spasm.

The patient should be discharged to the Thyroid Clinic for follow up.

* * *

The following outline, based on the preceding instructions, has been prepared for the guidance of interns and residents in the care of patients with diseases of the thyroid gland requiring operation. It is recommended that frequent reference for details and reasoning be made to the more complete instructions, a copy of which is on each ward.

CARE OF PATIENTS REQUIRING THYROIDECTOMY

The operative risk of each patient should be determined Class A (good), Class B (medium), and Class C (poor). Symbols: + = obligatory, * = advisable.

PREOPERATIVE ROUTINE

Class			
A	B	C	
+	+	+	Full iodination in thyrotoxicosis
		• +	Prolonged bed rest.
+	+	+	No operation in presence of infection or recent sulfonamides
+	+	+	Nutrition: high protein, carbohydrate and vitamin intake
		• +	Consultation concerning throat condition
		• • +	X ray films of thyroid gland and chest.
		+	Electrocardiogram
		• +	Quinidine, except in presence of persistent fibrillation
		+	Digitalis in persistent fibrillation failure or impending failure
+	+	+	Reassurance
		+	Medication (see detailed instructions)
		+	Consultation concerning anesthesia
		• •	Trial of medications, if local anesthesia is to be used

* * * Preoperative transfer to surgical ward for two to three days, the patient's condition being weighed by consultation between the services.

+ + + When hyperthyroidism is diagnosed on medical service, surgical resident to be notified.

+ + + No operation in presence of psychotic state.

OPERATIVE ROUTINE

- (1) Enema only if needed, and then always the night before.
- (2) Sedation the night before.
- (3) Preparation to be done the morning of operation; to be completed not later than fifteen minutes after the initial medication.
- (4) Preoperative medication. Nitrous oxide, oxygen and ether: 1/6 gr. morphine and 1/150 gr. atropine; Nembutal permissible. Local: Nembutal and morphine, starting one and a half to two hours before operation, in doses depending on the somnolence desired.
- (5) Operation to be postponed or discontinued if response to preoperative medication unsatisfactory, if anesthetic agent not tolerated (cyanosis not relieved by intratracheal tube or pulse or blood pressure

over 160), if respiratory difficulty (under local anesthesia) or if change in voice (under local anesthesia).

POSTOPERATIVE ROUTINE

MEDICAL PROGRESS

DIGITALIS, EDEMA AND DIURETICS*

A. STONE FREEDBERG, M.D.,† AND HERRMAN L. BLUMGART, M.D.‡

BOSTON

DIGITALIS

THE proper use of digitalis requires a clear understanding of the strength of the preparation used. It is unfortunate, therefore, that considerable confusion and misunderstanding prevail at the present time. The meaning of the descriptive terms by which the strength of the various marketed preparations is described on the label and the potency of these preparations when administered to patients have been discussed by various authors¹⁻⁵ in recent years, but it would seem worth while at this time to review the present status of the situation.

The eleventh revision of the *United States Pharmacopoeia* now in use§ went into effect in 1936 and attempted to make the potency of the digitalis preparations employed in the United States

comparable to that used in other countries; the strength of digitalis was defined in terms of the "international standard reference powder" of the League of Nations. The international reference powder was assayed by the cat method; the official method of assay of *U.S.P. XI* is the one-hour frog method. It was generally believed that the change made in *U.S.P. XI* would lead to an increase in potency to 125 to 130 per cent of the digitalis official in the preceding pharmacopoeia. Biologic assays as well as clinical experience have shown, however, that the increase in potency was greater than anticipated and amounted to as much as or more than 50 per cent. This increased potency of digitalis of *U.S.P. XI* has not been fully appreciated by many physicians and has led to frequent toxic reactions. The situation was, and still is, further complicated by the fact that, although certain manufacturers have continued to market digitalis of the potency of *U.S.P. X*, others have increased the strength of their preparations to approximately 150 per cent in an attempt to conform to *U.S.P. XI*. It is important, therefore, that the physician note whether the potency of the digitalis that he prescribes is described in terms of *U.S.P. X* or *U.S.P. XI*.

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, Vol. III, 1942* (Springfield, Illinois: Charles C Thomas Company, 1942. \$5.00).

*From the Medical Service, Beth Israel Hospital, and the Department of Medicine, Harvard Medical School.

†Assistant in medicine, Harvard Medical School; associate in medical research and junior visiting physician, Beth Israel Hospital.

‡Associate professor in medicine, Harvard Medical School; director of medical research and visiting physician, Beth Israel Hospital.

§Since this paper was submitted for publication, *U.S.P. XII* has become official. The potency of digitalis *U.S.P. XII* is stated elsewhere in this paper.

Apparently to avoid these difficulties, some manufacturers simply state the strength of the preparation in terms of cat units without reference to the pharmacopoeia. Although the cat method of assay has advantages and more nearly parallels the therapeutic potency in man than assays by the one-hour frog method, many variables are inherent in the technic. Among these are the depth and type of anesthesia, the speed of injection and the inherent differences of various cats, which can be only partially negated by using a series of animals. One must recognize, moreover, that preparations of the same potency in regard to their ability to kill a cat may vary markedly in their therapeutic activity in man. This is partly because the cat method of assay involves intravenous injection and consequently fails to distinguish between absorbable and nonabsorbable material. Thus, although it may require 15 to 25 cat units of digitalis leaf or tincture to digitalize a subject by mouth, 3 cat units of digitovin—*digitaline crystallisee* (*Nat. velle*)—will accomplish the same result.⁶ In this connection, Gold et al.⁷ have recently described a method of bioassay of digitalis preparations in man which, if adopted, would ensure greater uniformity in the clinical potency of the preparations available to physicians.

The degree to which powdered leaf or tincture of digitalis deteriorates is of practical moment and has been ably studied by Gold and his associates.⁸ It has been shown repeatedly that when the tincture of digitalis is stored for months, it loses potency according to the frog method of assay. This loss may amount, within three or four months, to as much as 50 per cent. As these authors remark, physicians appear to have been misled by the method by which the loss of potency was revealed, for, according to the cat test, the tincture retains its previous strength. Tests made with a very old tincture that had "deteriorated" by the frog method showed full strength in human beings.

In the forthcoming twelfth revision of the *United States Pharmacopoeia*, a new reference powder, standardized by the cat method of assay, will be employed. The potency of digitalis will be approximately 125 per cent greater than preparations in use prior to 1936. In general, therefore, if 15 gm of powdered digitalis leaf of *U.S.P. X* is considered to be the approximate amount necessary to digitalize a 150 pound patient, only 1.0 gm of the *U.S.P. XI* preparation is necessary, whereas 1.25 gm will be required according to the forthcoming *U.S.P. XII*. In clinical practice, 1.0 gr. of powdered digitalis *U.S.P. XI* three times a day for three to eight days, followed by 1.0 gr., five to eight doses a week according to individual requirements, will usually accomplish effective digitalization. It

should be recalled that satisfactory clinical digitalization in any given case does not imply reaching a point, but rather a range, which may be from 40 to 75 per cent of the toxic dose.⁹

The changes to be made in *U.S.P. XII* will remove much confusion and lead to a more uniformly potent preparation. It should be remembered, however, that the variations in dosage requirements by different patients are also considerable, so that proper clinical practice will depend, as it has since the time of Withering, on the ability of the clinician to know when the therapeutic effect has been achieved and to discontinue medication when the patient experiences anorexia.

Newer Digitalis Preparations

The difficulties with standardization and the unabsorbability of certain fractions of whole leaf digitalis from the gastrointestinal tract in man already mentioned point to the need for pure crystalline chemical substances having the properties of digitalis and suitable for oral administration. Chemically pure crystalline substances can be prescribed in terms of weight of the drug, thus obviating the necessity for biologic assay. Stoll¹⁰ in 1937 described the methods of isolation and crystallization of three glycosides from *Digitalis lanata*. These are known collectively as Digilamid and separately as lanatosides A, B and C. Many reports¹¹ in Europe and several in this country^{12, 13} show that Digilamid, which is a mixture of lanatosides A, B and C in constant proportions, in doses of 0.2 mg, is equivalent to and interchangeable with 0.065 gm or 1.0 gr of whole leaf digitalis *U.S.P. XI*.

Reports are also available^{14, 15} dealing with one of these lanatosides, namely, lanatoside C. In man, each milligram of this drug is equivalent to 0.17 gm or 2.6 gr of whole-leaf digitalis.¹⁶ Fahr and LaDue¹⁷ used lanatoside C in 256 patients with congestive failure and noted that the drug produced rapid and effective clinical responses, whether auricular fibrillation was present or absent. Toxic reactions were rare, and a few patients who were unable to tolerate digitalis took the drug with a good therapeutic result. The oral dose necessary to accomplish therapeutic digitalization¹⁸ averaged 60 to 75 mg. (12 to 15 tablets) over a period of forty-eight to seventy-two hours, and the maintenance dose was 0.5 to 2.5 mg. (1 to 5 tablets), average 1.5 mg. (3 tablets). The full digitalizing dose of lanatoside C by intravenous injection is about 1.5 mg. given within two or three hours. The much larger oral dose necessary to achieve digitalization indicates that the absorption of this drug from the gastrointestinal tract in man is quite imperfect. Aside from the uniformity of the preparation, Digilamid and lanatoside C pos-

ness no convincing superiority over powdered digitalis or tincture digitalis *U.S.P.* for gradual digitalization of the majority of patients. The above advantage of uniformity, moreover, is negated if the physician confines himself to the use of a preparation of digitalis with whose pharmacologic properties he is familiar.

Digitoxin has been used in Europe for many years, but has not been used extensively in this country. Gold and his associates^{9, 20} recently published the results of a study of the use of this drug in 213 unselected patients with varying degrees of congestive heart failure. It was shown by them that the drug is practically completely and rapidly absorbed from the gastrointestinal tract, the average oral and intravenous dose for full digitalization in man equaling 3.0 cat units or 1.25 mg. Digitalization by the oral method is complete in from six to ten hours. The classic studies of Hatcher and his collaborators, Eggleston and Weiss,^{21, 22} have amply demonstrated that digitalis emesis as commonly encountered after repeated small doses is not the result of local irritative effects on the stomach, but is due to afferent impulses from the heart or a direct action on the central nervous system. Gold²⁰ has shown, however, that when large doses are given, the local emetic action on the gastrointestinal tract may assume importance. This effect may be largely obviated by using digitoxin. Only about 2 per cent of the patients given a full single digitalizing dose of digitoxin become nauseous or vomit, whereas approximately 20 per cent of patients given a full digitalizing dose of whole-leaf digitalis present toxic manifestations. It is apparent, therefore, that digitoxin represents an excellent drug for rapid oral digitalization. The cost is considerably higher than that for an equivalent amount of whole-leaf digitalis.

Ouabain, a pure glycoside, although long in use, only now is to be included in the twelfth revision of the *United States Pharmacopeia*. Poorly absorbed from the gastrointestinal tract, it is suitable only for intravenous or intramuscular injection. An intravenous injection of 0.25 mg. repeated once or twice at intervals of two hours may produce dramatic relief of the symptoms of heart failure, and in patients with auricular fibrillation may reduce the heart rate from a level of 150 to 70. The drug is therefore useful in the occasional patient who has not been treated with digitalis and in whom rapid digitalization parenterally may be necessary. The view that strophanthin given intravenously produces effects not obtainable by digitalis has won widespread acceptance in Europe and has recently been propounded in this country. No convincing evidence exists to support such a view, provided suitable measures are invoked to

assure adequate doses of digitalis reaching the circulation.⁵

The purified mixtures of digitalis glycosides, such as digifoline, are widely used and fill a definite need when parenteral administration is indicated. It must be remembered that the digitalizing dose of digifoline, given intravenously or intramuscularly, is far less than the oral dose; thus it may require only 3 to 6 cat units of the drug intravenously to digitalize a patient. Oral administration of digitalis meets the requirements of the vast majority of cases, and the indiscriminate use of digitalis preparations parenterally is to be discouraged.

In all digitalis preparations so far studied, including lanatoside C and digitoxin, no significant difference is apparent in the margin between toxic and therapeutic doses.

In this country, chemists have succeeded in combining one molecule of a genin obtained from a squill's glycoside with two molecules of theophylline. It has been shown in cats²³ that the lethal dose of this theophyllinated genin is much larger than that which might be expected on the basis of the amount of genin used in its preparation. Changes in the ST segment appear in a far lower percentage of animals given the theophyllinated genin than those given digitalis. Such a drug may prove to be useful, but further experience will be necessary to determine its value in clinical practice.

The activity of digitalis, strophanthin and squill depends on the presence of an unsaturated lactone in the molecule. Recently Krayner et al.²⁴ showed that certain simple, synthesized, unsaturated lactones have a definite pharmacologic effect on the frog heart, producing an increase in amplitude followed by a period of diminished relaxation of the ventricle which terminates in systolic standstill.

Certain recent studies of the effect of digitalis on auricular fibrillation are of interest. In digitalizing patients with auricular fibrillation, one of the objects of therapy is to reduce the ventricular rate. It was shown many years ago²⁵ that patients with auricular fibrillation given ordinary therapeutic doses of digitalis would nevertheless show a much greater rise in pulse rate in response to exercise than normal persons of the same age group. This acceleration, which can be reproduced by the administration of atropine sulfate,²⁶ is the cause of considerable discomfort, shortness of breath and a sense of palpitation. Recently, however, evidence has accumulated^{26, 27} to show that this inhibition of the vagal effect on effort may be reduced by larger doses of digitalis. It is apparent that digitalis maintains a slow ventricular rate by the summation of two factors, one a

vagal factor abolished by atropine, the other an extravagal factor not abolished by atropine. In patients with auricular fibrillation and mild symptoms of congestive failure, it is advisable to digitalize to such a degree that exercise or emotion results in but a relatively slight increase in ventricular rate. The necessary dose may be quite close to that which induces impairment of appetite and nausea.

To summarize, it is incumbent on the physician to understand clearly the changes in the potency and dosage of the digitalis preparations in the light of recent developments. The variations that exist in dosage and potency of various preparations of digitalis make it advisable for the physician to utilize a single preparation with whose action and potency he is familiar. In a patient whose optimum maintenance dose is well regulated on one product, indiscriminate shifting to another preparation of different potency may lead to untoward effects. While certain purified crystalline preparations of digitalis possess the advantages of uniformity and obviate the necessity for bioassay, they possess no advantages over the *U.S.P.* powdered leaf or tincture in the treatment of the majority of patients. The increased cost of these preparations to the patient should be considered by the physician, since prolonged administration is usually necessary. In the unusual case where rapid digitalization is necessary, purified preparations such as Digitoxin are superior for rapid digitalization by mouth, and the other purified preparations previously mentioned are likewise suitable for intravenous administration. In all cases where rapid digitalization by mouth or parenteral therapy is employed, it is necessary to be certain that the patient has not received any digitalis preparations within the preceding ten or more days. If such preparations have been taken, the exact dose and strength should be ascertained. In the last analysis, clinical assay of any particular product must be done on the patient. Persons vary so greatly in their responses to and requirements of digitalis that one must look to the patient to determine the exact dose of digitalis.²⁸

EDEMA AND DIURETICS

The important considerations in the treatment of congestive failure are bed rest, digitalization, salt and water intake, and diuretics. Concerning the latter two, certain recent publications are of interest and practical import.

It is well known that the administration of sodium chloride will, under certain circumstances, result in clinical edema.²⁹ When the water changes affect chiefly the extracellular fluids, it has been

shown that the base simultaneously retained or lost is sodium.³⁰ There is, therefore, good reason for rigid restriction of sodium chloride in congestive failure. Schroeder³¹ has demonstrated that satisfactory diuresis, as evidenced by loss of weight, could be obtained in patients with congestive heart failure if the salt intake was maintained at 1 gm. or less daily. Conversely, with fluid intakes of 2500 cc. daily, no gain in weight occurred unless the salt intake was greater than 1 gm. daily. More recently, Proger et al.³² have demonstrated that the physical signs of congestive failure—edema, elevation of venous pressure, increase in circulation time and so forth—may be induced in cardiac patients if the salt intake is high enough. It is thus apparent that one of the advantages of the Karell diet is due to the fact that 800 cc. of milk contains approximately 1 gm. of sodium chloride. Diets containing less than this amount daily are generally inadequate in protein and therefore are to be used for only short periods of time. Nutritional edema not infrequently is overlooked in patients with congestive failure and is particularly prone to occur because of anorexia, albuminuria or frequent paracenteses. The loss of protein to the tissues when edema fluid is forming and the dilution of the blood protein consequent to the increase in plasma volume that occurs in congestive failure are likewise significant.³³ A diet containing 1 gm. of sodium chloride and an adequate amount of protein is shown in Table 1. This diet should be supplemented by vitamin B complex. Fluids may be allowed freely, except when renal failure is present.

Potassium chloride. In some patients, satisfactory diuresis may be obtained with a low-salt intake if potassium chloride is administered in doses of 3 to 5 gm. daily. This can be conveniently placed in a salt shaker and given to the patient to use with his low-salt diet.

Xanthines. Since the introduction of the mercurial diuretics, the use of the xanthines in the treatment of edema has been somewhat neglected. It must be stressed, however, that in many patients with congestive failure and slight to moderate amounts of dependent edema, satisfactory diuresis can be obtained and maintained by the oral administration of enteric-coated theobromine or theophylline sodium acetate. In some of these patients, attacks of cardiac asthma tend to occur whenever slight edema or latent edema occurs. The continued use of the xanthine diuretics under such circumstances may result in conspicuous improvement. Gastric symptoms are rarely encountered with these drugs except when doses in excess of 1 gm. four times daily are administered. Rise-

man and Linenthal³⁴ recently reported beneficial results in 2 patients with congestive failure who were treated for long periods of time with enteric-coated theobromine sodium acetate. In massive edema, however, the xanthines are of little value and mercurials or paracentesis or both must be utilized.

Urea. In refractory cases of edema, urea in doses of 60 to 90 gm. daily, in divided doses, may result in satisfactory diuresis.³⁵ The drug may also be used when mercurial diuretics are contraindicated, as in renal failure or acute inflamma-

persons, the danger of deposition of the mercurial agent in the fatty tissue and of resultant slough is obvious. The intravenous route may result in venous thrombosis. The rectal route, even when the suppositories are coated with a local anesthetic, occasionally results in marked inflammation and consequent pain and discomfort. To the ambulatory patient, therefore, an effective oral mercurial diuretic would be a boon. Calomel was the first mercurial preparation used for this purpose.¹¹ However, diuresis following its use was often unsatisfactory and poisoning sometimes oc-

TABLE 1. *Sample Diet Containing 2000 Calories and 1.0 Gm. of Sodium Chloride.**

BREAKFAST		FOODS TO BE AVOIDED		FOODS TO BE USED FREELY (except for caloric content)	
1 orange or ½ grapefruit or ½ cup orange or grapefruit juice		All salted, brined, corned, pickled and smoked foods		Salad oils and fats (chicken fat, lard and so forth)	
Dark cereal — 30 gm dry (shredded wheat, oatmeal or enriched cream of wheat)		Salt, pepper and paprika		Sugar, syrups, jelly and candy	
Cream (20 per cent) — 120 gm		Bacon and ham		Arrowroot cookies	
Salt free butter — 5 gm		Meat soups, broths and gravies		Flour (in small amounts for cooking)	
Sugar		Shellfish			
Coffee		Milk, cheese (except cottage cheese) and ice cream			
LUNCH		Vegetables of high salt content, such as beets, celery, sweet potato and greens (including lettuce and spinach)			
1 egg or 30 gm cottage cheese		Bananas			
Macaroni or rice — 30 gm dry (optional)		Crackers			
Enriched white bread — 1 slice (30 gm)		Molasses			
Vegetable — 100 gm serving (raw or cooked)					
Salt free butter — 15-30 gm					
Fruit — 100 gm serving					
Sugar or jelly					
Tea as desired					
DINNER		PERMITTED FRUITS (fresh or canned)		PERMITTED VEGETABLES (fresh or canned)	
Meat or fish or fowl — 120 gm (fish should be plain white fish, such as haddock or halibut)		Apple		Asparagus	
Potato (white) — 150 gm		Apricot		Brussels sprouts	
Vegetable — 100 gm serving (raw or cooked)		Blueberries		Beans (lima)	
Enriched white bread — 1 slice (30 gm)		Cantaloupe		Beans (string)	
Salt free butter — 30 gm		Cherries		Cabbage	
Fruit — 150 gm		Grapefruit		Carrots	
Cream (20 per cent) — 30 gm		Grapes		Cauliflower	
Sugar and coffee as desired		Lemon		Corn	
Potassium chloride, 3 to 5 gm, supplied in a salt shaker, may be added to this diet.		Peach		Eggplant	
		Pear		Onions	
		Pineapple		Parsnips	
		Raspberries		Peas	
		Rhubarb		Potatoes (white)	
		Strawberries		Pumpkin	
		Watermelon		Squash	
				Turnips	
				Tomatoes	
APPROXIMATE CONTENT		Calculation of this diet was based on tables in Stern's <i>Applied Dietetics</i> supplemented by figures from Pattee's <i>Dietetics</i> (1940 ed.).

Calcium	0.5 gm.	Calories	1970		
Phosphorus	0.96 gm				
Iron	0.011 gm				

*We are indebted to Mrs. Marie Alexander for planning this diet.

tory conditions of the kidney or both. It is best given three times daily, immediately after meals, in ice-cold solution. The unpleasant taste may be masked by solution in syrups, such as acacia, or fruit juices. After several days of administration, the blood nonprotein nitrogen should be determined to ascertain whether the urea is being properly excreted. In almost all cases of congestive heart failure, however, the drug is readily excreted, carrying with it large quantities of water.³⁶

Mercurial diuretics. The action of the mercurial diuretics is directly on the kidney, causing diuresis by a reduction in tubular reabsorption of water.³⁷⁻⁴⁰ They may be administered intravenously, intramuscularly, rectally or orally. In obese

persons, the danger of deposition of the mercurial agent in the fatty tissue and of resultant slough is obvious. The intravenous route may result in venous thrombosis. The rectal route, even when the suppositories are coated with a local anesthetic, occasionally results in marked inflammation and consequent pain and discomfort. To the ambulatory patient, therefore, an effective oral mercurial diuretic would be a boon. Calomel was the first mercurial preparation used for this purpose.¹¹ However, diuresis following its use was often unsatisfactory and poisoning sometimes oc-

curred. Since theophylline favorably influences the diuretic effect and toxicity of parenterally administered mercurial diuretics, Chrometzka⁴² and Görl⁴³ used the combination orally. Further studies in this country by Batterman et al.,⁴⁴ using Salyrgan-theophylline in enteric-coated tablets, have shown that a satisfactory diuresis could be obtained in 72 per cent of the fifty-six trials in 29 patients. The usual loss of weight was 3 to 5 pounds, although occasionally the loss was above 8 pounds. With parenteral mercurials, on the other hand, weight losses of 8 pounds or more are common. As in the case of the parenteral preparations, the previous administration of ammonium chloride, 4 to 6 gm. daily, and digitalis in-

creases the effectiveness of the oral preparation. Borg⁴⁵ has confirmed these results in a study of 39 patients, of whom 29 obtained a good diuresis. Toxic symptoms observed included nausea, vomiting, abdominal discomfort, pain and general weakness. In 3 cases, the drug had to be discontinued because of severe diarrhea; in the remainder, the symptoms were transient and the drug could be continued. No evidences of kidney irritation or of blood disturbances were noted. The oral dose recommended is 2 tablets three times daily at the beginning of treatment, with a reduction in the dose to an amount necessary to prevent reaccumulation of the edema.

Toxic reactions to mercurial diuretics. In the past several years, acute mercury poisoning and 27 deaths have been ascribed by various authors⁴⁶⁻⁵⁰ to the mercurial diuretics—Salyrgan, Mercupurin, and Esidrone. The toxic symptoms varied from slight dyspnea and orthopnea to syncope, pallor, shallow respiration and slow (20 to 30 per minute) pulse rates. In several cases, death occurred within one or two minutes after the injection was completed. Although in most cases the route of administration was intravenous, in at least 1 case toxic symptoms occurred after rectal administration. The mechanism of death due to mercurials in animals is mainly that of a direct toxic effect on the heart.⁵¹ Electrocardiograms show depression of the T waves, runs of extrasystoles, ventricular tachycardia and, terminal, ventricular fibrillation. The incidence of such toxic symptoms must be extremely small, since although millions of doses have undoubtedly been administered, the number of deaths is few.

To summarize, rectal administration of the mercurials is frequently indicated and, except in extremely edematous or obese patients, the mercurials are better given intramuscularly than intravenously. If the drug is to be given intravenously, it should be diluted to 20 cc. and administered slowly. If given rectally, a small enema should precede the insertion of the suppository. The latter should be coated with an anesthetic ointment, such as nupercaine or pantocain. Although the possibility of mercury poisoning is slight, constipation should be prevented in patients receiving mercurials. It must be further remembered that many patients can be treated with xanthines after they have been rid of most of the edema fluid. In patients with considerable accumulations of edema fluid who have previously been digitalized, a marked diuresis may lead to the signs and symptoms of digitalis toxicity, which can readily be avoided by prior reduction in dosage. Christian⁵² has cautioned that in older men who have prostatic involvement it is wise to remember that an active

diuretic response may overdilate the bladder and precipitate symptoms of acute urinary obstruction. In this type of patient, constant catheter drainage during the stage of active diuresis may well be a prophylactic procedure that may obviate a forced prostatectomy.

CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITALANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

CASE 28491

PRESENTATION OF CASE

First admission. A twenty-seven-year-old mill-worker entered the hospital for the first time because of pain in the right knee.

Two weeks before admission the patient developed an intermittent dull pain in his right thigh and knee, which was more severe on walking. One week later he began having two or three watery stools each day. Three days before entry he became constipated. He had not noted any blood or mucus in the stools.

Four years before entry he was operated on for acute appendicitis at another hospital, and tuberculous peritonitis was found; the appendix was removed. He had had no subsequent symptoms.

Physical examination showed a well-developed, undernourished man complaining of pain in the knee. Examination of the heart and lungs was negative. In the right flank was a hard, fixed, nontender mass about 5 cm. in diameter. The right knee was painful on extension, but no definite cause could be discovered.

A barium enema showed that the cecum was irregular in outline and immovable. At the end of six hours the cecum was incompletely visualized. A chest roentgenogram was negative. In view of his past history, a presumptive diagnosis of tuberculosis of the cecum was made, and he was sent to a sanatorium.

Second admission (twelve years later). He remained in the sanatorium for fourteen months, during which period his weight increased from 110 to 170 pounds. He was seen in the Out Patient Department of this hospital three years after his discharge from the sanatorium; he appeared very well, was free from symptoms and was able to do heavy work. He was examined four years later and was still in excellent health.

Four weeks before re-entry, — the patient was then thirty-eight years old, — he was seen in the Out Patient Department because of a lower abdominal ache and urinary frequency of two weeks' duration. Cystoscopy revealed "whitish specks" scattered over the bladder mucosa which were suggestive of chronic cystitis. The urine showed

a very slight trace of albumin, and the sediment contained 2 to 4 white cells and large clumps of bacteria per high-power field; culture revealed only a few colonies of *Staphylococcus albus* and diphtheroids. Two days later he developed a pain in the right flank, which radiated around into the right lower quadrant. Roentgenograms of the abdomen showed an area of bony condensation close to the right sacroiliac joint, that did not shift in position in various films. An intravenous pyelogram showed prompt excretion of the dye on both sides; on the left, the kidney pelvis and ureter were normal, but on the right, there was slight but definite dilatation of the kidney pelvis and of the upper half of the ureter down to the area of condensation described in the bone. Because of the organisms found in the urine culture the patient was treated with methenamine. Two weeks before entry he gradually began to feel weak, and occasionally had cold sweats and shaking chills at any time of the day. He often vomited half an hour after eating; no blood or coffee-grounds material was noted. He continued to have daytime frequency without hematuria, and nocturia three or four times. He denied dysuria, urgency, incontinence, dribbling or the passing of urinary stones. At the time of admission he was very uncomfortable because of a dull ache in the right flank and right inguinal region and because of inability to retain food. During the four weeks of illness he had lost 22 pounds. He denied any change in bowel habits but stated that four weeks before entry he had passed a small amount of fresh blood just once.

The family history was noncontributory. The patient had lived in Massachusetts all his life and worked as a wool carder.

Physical examination revealed a well-developed but tired-looking man who was moderately uncomfortable. He belched frequently. A few small nontender lymph nodes were felt in each groin. Examination of the lungs and heart was normal. In the right lower quadrant just to the right of the midline there was slight fullness, and just above the inguinal ligament a poorly outlined, hard, fixed, tender mass about the size of a grapefruit, which was dull to percussion. No other masses were felt. There was constant pain in the right costovertebral angle on deep pressure. On rectal examination the mass in the right lower quadrant was felt.

The blood pressure was 130 systolic, 85 diastolic. The temperature was 101.6°F., the pulse 90, and the respirations 20.

Examination of the blood revealed a red-cell count of 4,750,000 with a hemoglobin of 80 per cent and a white-cell count of 22,500 with 90 per

cent polymorphonuclears. The urine was acid in reaction, had a specific gravity of 1.015 and gave a + test for albumin; the sediment contained 5 red cells and 25 white blood cells per high-power field. When repeated, no proteinuria was found, and only an occasional red blood cell and white blood cell were seen in the sediment. The stools were loose, and one stool examined for blood was negative. The nonprotein nitrogen was 24 mg., and the total protein 5.5 gm. per 100 cc.; the blood chloride was 99 milliequiv. per liter.

A flat plate of the abdomen showed an ill-defined soft-tissue mass pressing on the air-filled cecum. There were several slightly dilated air-filled loops of small intestines seen in the right side of the abdomen. The distention was not very marked. The psoas shadows were clearly visible. The upper portion of the right sacroiliac joint was poorly outlined and less dense than that on the left. An x-ray film of the chest revealed that the right diaphragm was slightly high in position. There was no evidence of fluid. The lung fields were clear.

On the day after admission the patient's temperature rose to 104°F., and two days later he had a chill, after which the temperature rose to 103.4°F. Vomiting continued during hospitalization, and loose watery stools occurred each day. On the fourth day after admission the abdominal mass seemed larger and the abdomen was more distended. There was increased spasm of the abdomen, particularly on the right.

An operation was performed on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM B. BREED: There are three approaches here—three points of view that one might take. One is that the etiology of the patient's illness over a period of more than twelve years is the same. Another point of view is that there were two entirely separate episodes in his medical career; the third is that there may have been some mechanical defect produced during the first illness which may have complicated the final outcome.

Let us examine the first thesis, to see if it is reasonable to suspect that this was all due to one cause. We see that a presumptive diagnosis of tuberculosis was made. I should like to know who made the diagnosis of tuberculous peritonitis four years previously when he was operated on for appendicitis. I think that the observation must be established as a correct one before one can even make a presumptive diagnosis of tuberculous cecum. Moreover, my impression is that tuberculous peritonitis and colonic tuberculosis are not

often seen in the same patient. Is that correct, Dr. Holmes?

DR. GEORGE W. HOLMES: I do not believe I am competent to answer that question.

DR. BREED: Does one find tuberculous peritonitis often in the presence of gastrointestinal tuberculosis?

DR. HOLMES: I should say not.

DR. FLETCHER H. COLBY: We have had several patients lately who have had tuberculous lesions of the small and large bowel, and none of these have had tuberculous peritonitis.

DR. BREED: That is my impression, but my experience is not very broad. What would you say, Dr. Mallory?

DR. TRACY B. MALLORY: I think your statement is true.

DR. BREED: He may have had tuberculous peritonitis. We have often been told that exploration clears up the peritonitis, but I have never been very convinced that that is true. Also, I should like to cast some doubt on the diagnosis of peritonitis of tuberculous origin. I should also like to ask the roentgenologist if he was sure that the patient had tuberculosis of the cecum. Would you be willing to look these films over now, Dr. Holmes?

DR. HOLMES: They are not here; they were destroyed.

DR. BREED: The trouble is, that when the patient came in the second time, no observation was made on the cecum or colon by barium so we do not know if he had a defect in his cecum—he may have been too sick for such an investigation. All we have at the last admission is the flat plate.

Of course anybody going to a sanatorium and sitting around in the sun gains weight and feels better, and the fact that the patient got well does not really decide the question whether he had tuberculosis. At the time he came in with a sore knee and they were making a presumptive diagnosis of tuberculosis, they did not take an x-ray film of the knee; so that leaves us in the dark. There are no x-ray films here? Although no x-ray films were taken, it was thought that he had tuberculosis of the knee or hip.

DR. HOLMES: From the description of the examination of the colon at that time it is suggested that the cecum was spastic. This is usually seen in ulcerative tuberculosis. The ulcerative type is usually accompanied by some pulmonary lesion, which the patient did not have.

DR. BREED: I am about to cast considerable doubt on the diagnosis of tuberculosis of the cecum. Although he had had pain in the right flank previously and also had a rather sudden onset of right flank pain on the second admission, he had been

so well during the intervening twelve years, and able to do heavy work, that I am rather inclined to think these were two separate episodes and that there was no common etiology. I shall take that stand.

Concerning the third point of view that I mentioned, whether there was some defect on which this infection was superimposed, I have as yet no opinion.

Have we any x-ray films taken during the second admission? Will you tell me something about the bony condensation and so forth?

DR. HOLMES: Apparently, these films were all taken at about the same time. Certainly the chest shows no evidence of tuberculosis. The diaphragm is a little high on the right, but that does not strike me as being remarkable. The liver shadow is large rather than small, but not definitely outside normal limits. I suspect the patient had a little enlargement of the liver. So far as the urinary tract is concerned, I can see the pelvis of the kidney on the right side very well. The fact that that remains filled and the whole ureter remains filled and the other side empties, suggests an obstruction of the ureter. That is the only concrete finding. The dilatation is certainly very slight. The statement of condensation in the bone does not impress me at all. I do not see anything that I would be convinced was abnormal. I do not know what they meant.

DR. BREED: It did not mean anything to me.

DR. HOLMES: It is an unusual term.

DR. BREED: And moreover, it is not there, whatever it is.

DR. HOLMES: That is right. Apparently the patient had a marked dilatation of the small bowel. A Miller-Abbott tube was inserted, and this film was taken to show the position of the tube. There is a good deal of gas, and I do not believe it is confined to the large bowel. There is some in the small bowel, and a moderate degree of dilatation.

DR. BREED: Have you a flat film showing the soft-tissue mass in the flank?

DR. HOLMES: This might be the mass outlined by the gas in the colon.

DR. BREED: The sacroiliac joint is not diseased, but there is perhaps obstruction to the ureter—partial, not complete.

Would you please, Dr. Colby, interpret for me the statement, "Cystoscopy revealed 'whitish specks' scattered over the bladder mucosa, which were suggestive of chronic cystitis"? Was there any suggestion of tuberculosis?

DR. COLBY: It means very little to me. From this description there is nothing in the bladder that is typical of tuberculosis. In the first place, there were no ulcerations, and in the second place,

there is no description of the so-called "submucous tubercles," which are red areas with tiny white centers. The whitish specks could perfectly well be particles of exudate adherent to the bladder mucous membrane—that is all.

DR. BREED: I might say from reading this over that this man had a urinary infection. One sediment showed a few white cells but one showed nothing. Of course he could have had infection with an obstructed ureter on the right, without showing anything in the urine. That brings up a question we have to decide, that is, whether the lesion was in the gastrointestinal tract or in the urinary tract. That is my problem.

DR. COLBY: I think it is fair to assume that the patient had some urinary-tract infection because he had pus in his urine on at least two examinations and a positive culture. I do not know how the urine was taken; only a few *Staph. albus* colonies were found, which might be contamination or might mean something.

DR. BREED: Have you ever seen an abscess in the cecal region originating in the gastrointestinal tract that might produce, by spasm, some obstruction to the ureter like this?

DR. COLBY: Yes.

DR. BREED: It is reasonable to expect that, if there was an inflammatory mass in this region, the ureter would not empty normally?

DR. COLBY: A tumor or an appendix abscess will cause an obstructed ureter and hydronephrosis.

DR. BREED: That is what I am driving at, and it leads me to the conclusion that I had already come to, and had hoped to keep prominent, namely, that the lesion was probably not in the urinary tract but in the gastrointestinal tract.

If it was in the gastrointestinal tract, what kind of lesion was it? From all I can read here it seems to have been an abscess. The patient had chills, fever and a tender mass extending from the flank down to the right lower quadrant, with a white cell count of 22,500 and 90 per cent polymorphonuclears. He presented the so-called "acute surgical belly." Someone operated on him. I assume he was operated on by an abdominal surgeon and not by a genitourinary surgeon. It might have been difficult to decide what surgeon one would choose. I shall pick the abdominal surgeon. I think he operated and found some sort of abscess.

What was the source? It still is possible for the patient to have had an appendiceal abscess. The stump may not have been buried fourteen years previously and he still might have had some infection lurking there which flared up into an ab-

success. The story is a pretty good one for it. I admit that the time element is a long one.

I do not believe it is tuberculosis for reasons that I have already discussed.

Could the patient have had regional ileitis? He could and might have had regional ileitis.

Could he have had a retroperitoneal abscess? If so, what was the source of it? I cannot imagine.

I shall predict that the patient was operated on by an abdominal surgeon who found an abscess, the exact source of which I cannot designate and that he very likely got well and did not have any underlying pathologic lesion, such as cancer or lymphoma, in spite of the fact that small, non-tender lymph nodes were noted in each groin. We find such nodes frequently, and it does not disturb me. No tuberculosis, no cancer, no lymphoma—a pyogenic infection in the peritoneal cavity in the region of the cecum, the source of which is unknown. The patient may have had regional ileitis that perforated—but that diagnosis cannot be made.

DR. WILLIAM A. BISHOP: Examination of the right lower quadrant showed evidence of an old healed sinus. Is that to be connected? I saw him in the Out Patient Department. He had evidence of an old healed sinus in the region of the cecum.

DR. BREED: He had had appendicitis. Why do you say "healed sinus" rather than "healed scar"?

DR. MALLORY: There was a history that the sinus had drained for some months at the Lakeville Sanatorium. That should have been in the hospital record.

DR. BREED: I think it certainly should! The history of a draining sinus in a patient who had been in a tuberculosis sanatorium makes quite an impression on me.

DR. BISHOP: It did on me. That is why I sent him to the hospital.

DR. BREED: How often does one see a draining sinus with tuberculosis of the cecum?

DR. ROBERT R. LINTON: That has not been operated on?

DR. BREED: He had his appendix out.

DR. LINTON: I think it is not uncommon to see it immediately after appendectomy with a tuberculous cecum, but it is a little surprising that it healed if it was tuberculous.

DR. BREED: Even in a sanatorium?

DR. LINTON: Yes.

DR. BREED: But it did heal!

DR. BISHOP: And how do you account for the thigh and knee pain?

DR. BREED: I give up—no one was interested in it. They did not even x-ray the hip or knee.

DR. BISHOP: How about psoas irritation or abscess?

DR. BREED: Possibly psoas abscess; but the x-ray films show that the psoas muscles were clear.

DR. MALLORY: The sinus would be at least equally in favor of regional ileitis.

DR. LINTON: I think that is true, and such a sinus would be likelier to close up than a tuberculous sinus.

CLINICAL DIAGNOSIS

Intraperitoneal abscess.

DR. BREED'S DIAGNOSIS

Peritoneal abscess in region of cecum (pyogenic—? source).

ANATOMICAL DIAGNOSES

Malignant lymphoma, clasmatocytic type, of mesentery, involving ileum, cecum and sigmoid.

Ileosigmoidal fistula.

Retroperitoneal abscess.

Appendectomy wound, healed.

Sinus tract, healed.

Cystitis, slight.

Pyelonephritis, right, slight.

PATHOLOGICAL DISCUSSION

DR. MALLORY: This man was explored, and a huge tumor mass consisting mostly of enlarged retroperitoneal lymph nodes with obvious extension to several loops of bowel was found. A biopsy was taken, and the surgeon backed out as quickly as he could. Biopsy showed a malignant lymphoma of the reticulum-cell or clasmatocytic type. The patient went downhill very rapidly and died. At autopsy, we did find Dr. Breed's abscess in the retroperitoneal tissues.

DR. BREED: Thank you.

DR. MALLORY: That had not been found by the surgeon. There was a huge tumor mass, chiefly in the mesentery, which had invaded the cecum, a portion of the ileum and a portion of the rectosigmoid. There was a fistulous opening between the ileum and rectosigmoid so that the large bowel was entirely short-circuited. The liver contained many metastases, but the other organs—the spleen, lungs, kidneys and so forth—were free from metastasis. There was a mild grade of cystitis.

DR. BREED: Do you think the episode twelve years ago had anything to do with the last one?

DR. MALLORY: I think not. We found no evidence of tuberculosis at autopsy.

DR. HOLMES: Was the liver large?

DR. MALLORY: Quite, it weighed 2300 gm.

DR. BREED: Were the inguinal lymph nodes positive?

DR. MALLORY: No; they did not contain tumor.

CASE 28492

PRESENTATION OF CASE

A fifty-nine-year-old chauffeur came to the hospital because of diarrhea.

Approximately six months prior to admission he was first bothered by "gas," which usually occurred a short time after meals and was partially relieved by soda and ginger. Three months later a dull pain developed just below the umbilicus. His physician prescribed pills, but these were ineffectual in providing relief. Despite the pain the patient was able to work without great difficulty. During the illness his bowels moved regularly without cathartics. Five weeks before entry, because he was slightly constipated, he took a Seidlitz powder in the morning, and since there was no bowel movement, he repeated the dose several hours later. Soon after the second dose he began to have a loose bowel movement, and the diarrhea persisted up to the time of entry. With the onset of diarrhea the abdominal pain was relieved and did not recur. The diarrhea usually developed several hours after meals, but was most bothersome at night. It often occurred two or three hours after supper and lasted four or five hours. He believed that ingested fluids were evacuated twenty to thirty minutes later. With the onset of diarrhea the feces became very foul smelling but were never tarry or bloody. He had had rare attacks of cramps and said that his stomach "rolled" a great deal. During the five weeks prior to admission he had lost 15 to 18 pounds.

The family and past histories were noncontributory.

Physical examination revealed a well-developed and well-nourished man who appeared to be in good health. Examination of the lungs, heart and abdomen was negative.

The blood pressure was 126 systolic, 80 diastolic. The temperature was 97.8°F., the pulse 70, and the respirations 16.

The examination of the blood revealed a red-cell count of 4,100,000 with a hemoglobin of 11.5 gm. per 100 cc. The urine was normal. The stools showed a + guaiac test. The blood Hinton test was negative. The serum nonprotein nitrogen was 34 mg. per 100 cc., and the protein 5.8 gm. A barium meal and enema demonstrated a fistula between the third portion of the duodenum and the proximal third of the transverse colon.

An operation was performed on the third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD SCHIATZKI: It is easy to summarize the highlights of this history by saying that this was a patient with constant diarrhea of five weeks'

duration, during which period he had lost some weight. The diarrhea was superimposed on a six months' story of indigestion. X-ray examination demonstrated a fistula between the proximal transverse colon and the third portion of the duodenum.

In addition to the short x-ray description in the case history I have been given films taken in an outside hospital. These apparently represent two examinations—a barium enema, and a gastrointestinal series that was done on the following day. There is something wrong with the report in the record. It is obviously impossible that the patient could have had a fistula between the transverse colon and the third portion of the duodenum because these portions of the bowel never touch, at least not in this case. I suppose what the fluoroscopist meant was a fistula between the proximal transverse colon and the lower part of the second portion of the duodenum. At least the roentgenologist took a spot film over the area that he thought was the site of the fistula, and it corresponds to the area that I have just mentioned. On all these films taken during the enema the duodenum is filled apparently from the colon. And on the gastrointestinal series taken the next day the transverse colon is filled. The proximal transverse colon and the lower part of the descending duodenum are constantly in close proximity in all the films so that establishes the possibility of a fistula in this area. If there is a supposed fistula, one studies the area very carefully and looks for further abnormalities. In this respect, the films are very disappointing. The film of the colon shows no defect, and the duodenum in the area of the fistula appears normal. However, the reading of x-ray films of the gastrointestinal tract in patients whose fluoroscopy was done by someone else is a highly unreliable practice, and most radiologists abhor it. But I have to take what I get in this case.

Beyond the demonstration of a fistula, the existence of which we had already surmised from the history, the films do not give us any information. I might mention this small diverticulum in the third portion of the duodenum. I am sure it is irrelevant, however.

This patient supposedly had a spontaneous fistula between the proximal transverse colon and the second portion of the duodenum. What can cause such a fistula? I shall start by saying that this kind of fistula is much less common than one between the stomach and the colon; but it does occur and not too infrequently, and the usual cause is a cancer of the hepatic flexure of the colon. We have no evidence of such a cancer in these films and therefore have to throw out this commonest cause. As soon as we do this, we are confronted

with rare things. A cancer of the duodenum has been described as causing perforation into the colon, but we have no evidence of such a cancer. I can conceive of a neoplasm on the outside of the two organs perforating into both of them, but there is no evidence of such a lesion. The retroperitoneal structures are perfectly normal. I can conceive of a gallstone that had perforated into the colon and at the same time into the duodenum, thus forming an inflammatory mass that communicates with the colon and establishes a fistula between the three places. In such a case one would expect to see some air in the bile ducts; since I do not see it, that is out.

What remains is a very rare possibility, that of perforation of a benign peptic ulcer of the second portion of the duodenum. The history is suggestive. The patient had had symptoms for several months and was relieved by soda. The abdominal pain stopped very suddenly, and from then on he had diarrhea. This is almost a classic story of what happens in patients with marginal ulcer that secondarily results in the formation of a gastroduodenocolic fistula. The ulcers are very rare, but very occasionally a fistula in such a case has been described. I know of only two such cases in the literature. The most convincing one was described by Dr. C. N. McPeak,* of Fitchburg. Against such a diagnosis is the fact that we do not see any intrinsic bowel lesion in the area of the fistula. There is no induration of either the colon or duodenum. For want of a better explanation I should put this explanation first, but before concluding I must mention another possibility. When a fluoroscopist gives a barium enema, he does not usually see the barium go through the fistulous tract into the duodenum or stomach. He suddenly finds barium where it should not be and then traces it backward but does not necessarily find the place of the actual fistula. In other words we must consider the possibility that the fistula was not in the area that was examined and was lower down, somewhere beyond the ligament of Treitz. In such a case, carcinoma, or possibly lymphoma, is the commonest cause. Extremely rare cases of benign peptic ulcer of the jejunum have also been described, but this area is poorly visible on the films I have here. I cannot go beyond mentioning a fistula below the ligament of Treitz as a possibility. Certainly if someone brought these films to me with this report from an outside roentgenologist and said, "Shall I operate?" I should say, "Let me fluoroscope first."

A PHYSICIAN: I should like to ask Dr. Schatzki if a diverticulum of the duodenum can produce such a picture.

DR. SCHATZKI: I do not believe that a simple diverticulum can do it—unless something happens to it, that is, it becomes occluded by a foreign body. That is a possibility.

DR. WILLIAM B. BREED: I should like to ask Dr. Schatzki if he is willing absolutely to rule out cancer because he cannot see evidence of it by x-ray.

DR. SCHATZKI: If I had fluoroscoped this patient myself and was convinced that the intestine on both sides of the fistula was normal, I should exclude it. Just looking at the films I should have to make that restriction.

CLINICAL DIAGNOSIS

Duodenocolic fistula.

DR. SCHATZKI'S DIAGNOSIS

Ulcer of duodenum, with duodenocolic fistula.

ANATOMICAL DIAGNOSIS

Adenocarcinoma of colon, with jejunocolic fistula.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: Only the expert is acutely aware of the potential pitfalls of his technique. Dr. Schatzki was justifiably suspicious of the accuracy of the localization of the fistula and suggested that it might even be below the ligament of Treitz. If he could have been sure of this point he would have made a diagnosis of some form of malignant disease. At operation it was found that the fistula was actually some 15 cm. beyond the ligament of Treitz and connected the jejunum with the transverse colon. A large tumor mass involved all layers of the walls of the jejunum and the colon, with craterlike ulceration of the mucosa in each segment of the bowel. So far as the gross appearance was concerned, it could have been primary in either organ. It proved to be an adenocarcinoma, which gets us no farther, and we are forced back on the law of chances in attempting to decide where it was primary. Cancers do occur very exceptionally in this portion of the jejunum, and it is conceivable that it was primary there. On the other hand the chances are 1000 to 1 that it was primary in the colon.

DR. SCHATZKI: This case supplies the answer to a question that always arises when a patient has been fluoroscoped in an outside hospital. The question is, Should the patient be fluoroscoped again? We try to save the patient money and go ahead with the operation, but we should not do so, unless the findings are very obvious. We should fluoroscope again.

DR. MALLORY: Certainly it would have been worth while in this case.

*McPeak, C. N. Benign duodeno-colic fistula: with report of 2 cases. *Radiology* 34:343-350, 1940.

"THE MEDICAL CURRICULUM"

THERE is much mental food in an editorial under this title in the August 15 issue of the *British Medical Journal*. One senses that medical educators in England have been as violently disrupted in their thinking as in their physical plants and activities, but that they are beginning to pull themselves together and to look into the dark corners now illuminated by the wartime searchlights. One also senses that great and inevitable changes in the training of physicians are close at hand. A system that has been dominated by scientific investigators and successful consultants is producing too few general practitioners; it must turn back and concern itself more intimately with the knowledge and bodily skills required by the practicing

doctor. At the same time, it might acquire some of the methods of selection and training that have so markedly accelerated the acquisition of industrial skills during the war. The application of these changes should be integrated with a social and economic structure that will permit young men and women to marry freely at the age of twenty-three or twenty-four years; otherwise, the best stock may tend to be bred out of the race. Thus, the writer develops a rough outline of what the future British medical curriculum should provide for.

This startling revelation about medical education in Britain applies as well to the United States. Recent and present graduates are finding themselves in a world whose ideals and demands are proving very different from those of the schools in which they were trained. Often, the information they most urgently need was not emphasized in their undergraduate courses. The historical, and on that account obscure, fact that smallpox can be prevented by inoculation, for example, might these days become a primary piece of knowledge in an island garrison. The neglect of preventive opportunity of any sort will soon cease to be an omission; it will become an error of commission. Graduates in army practice will wonder why they were not taught this in medical school. The lungs with cavities, the livers with lumps and the various advanced degenerations of the retina may still provide teaching material, but they are not the stuff of which medical practice has been or will be made. They are the gross, the rare, the allegedly interesting, and contrast sharply with the trivial but common deviations that occupy most of the practitioner's time. As time goes on, the practitioner will want to know less about the museum and more about the conditions under which men should live, eat, sleep, work, love and play. How can they be taught to appraise these things?

How indeed? Certainly not by changing the curriculum, although that may well accommodate itself to the interests and activities of those who are currently responsible for it. The world of to-

day is moving into the hands of those who are active, dynamic, decisive—the “motor minds.” These people have always eschewed the deliberative, scholarly and somewhat cautious impulses that have built the academic past. As they now come into power, they may well change the facets of the medical-school curriculum, and polish them too, but whether the product can thereby be changed is another matter.

The constitutional pattern of a person may be either in harmony with or antagonistic to the environment in which he is called to function, and his performance consequently may be good or poor. Or more happily, he may possess an adaptable constitution, which will allow him to function well under a variety of conditions; this has always been the constitution of the good general practitioner, and has proved to be his great value in war. Britain has repeatedly called for general practitioners, not for specialists. An improved selective process, or series of processes, by which such persons could be screened away from the brilliant performers in narrow fields would make the greatest contribution to our systems of premedical and preclinical schooling. If it could have been applied to the prewar student body, there would be less indication for postwar revision of the medical curriculum.

VENEREAL-DISEASE CONTROL AND THE PHARMACIST

SINCE the passage of the Venereal Disease Control Act in 1938, the importance of the pharmacist as a factor in the control of venereal disease has achieved increasing recognition. This is to be expected because the pharmacist is often the first to be consulted by those who have, or suspect they have, a venereal disease.

The physician-pharmacist relation, which has existed in this country for many generations, is more than a mere tradition—it is a natural outgrowth of the close interdependence between physician and pharmacist in a common endeavor, namely, the healing of the sick. Thus both the

pharmacist and the physician bear a joint responsibility to society—to the people whose well-being depends greatly on their intelligent co-operation. The war effort has pointed up the individual responsibility of these allied health forces and, at the same time, has strengthened their interrelation in the united drive against diseases that sap the national strength.

Foremost among national health problems are the venereal diseases, which in World War I caused seven million days lost from service in the United States Army. As for the population generally, over 2 per cent of all persons have or have had syphilis. Although the actual prevalence of gonorrhea is not known, it is estimated that it strikes from three to seven times as often as syphilis.

A nationwide effort to eradicate syphilis and gonorrhea through a program of effective control is being co-ordinated by the United States Public Health Service. With funds appropriated by Congress and by state, city and county health departments, full-time professional workers have instituted vigorous health measures for the control of venereal disease. But no health-control project can be termed effective without the aid of the pharmacist.

The pharmacist himself is more aware than anyone else of his responsibility to the community in assisting the health authorities in the urgent task of bringing venereal-disease patients under proper treatment. A recent comment from the Public Health Service, published elsewhere in this issue of the *Journal*, emphasizes this responsibility. Through his professional organizations, notably the American Pharmaceutical Association, and with the co-operation of the American Social Hygiene Association, the pharmacist has demonstrated a willingness to take an active part in the national program for the control of syphilis and gonorrhea.

By participating in the program for venereal-disease control being promoted by the Public Health Service, by the state health authorities and by the Joint Committee of the American Social Hygiene Association and the American Pharmaceutical Association, the pharmacists of this coun-

try will strengthen public confidence in their profession. At the same time they will know personally that their efforts are being given toward the elimination of the venereal-disease scourge, both for the best interests of the civilian population and for the greater fighting efficiency of the armed forces of the Nation.

MEDICAL EPONYM

SIMMONDS'S DISEASE

The first reported case of hypophyseal cachexia was described by Professor Morris Simmonds (b. 1855) of St. George's General Hospital at Hamburg before the Medical Society of Hamburg on January 5, 1914. The paper was printed under the title, "Ueber Hypophysisschwund mit tödlichem Ausgang [Destruction of the Hypophysis with Fatal Outcome]" in the *Deutsche medizinische Wochenschrift* (40:322, 1914). A portion of the translation follows:

... The history of the illness is briefly as follows: A previously healthy woman suffers with severe puerperal sepsis. She develops a septic necrosis of the pituitary body. As a result of the loss of this vital organ there develop grave deficiency phenomena: menopause, muscular weakness, vertigo and attacks of loss of consciousness, anemia, rapid aging—in short, a "senium præcox." The remaining intact fragments of the gland gradually atrophy, being surrounded by connective tissue. The organ becomes entirely insufficient, and the woman dies in coma. Autopsy shows as the sole cause of death an almost complete disappearance of the hypophysis.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1941

HEMORRHAGE

Thirty-one maternal deaths that occurred in Massachusetts during 1941 were attributed to hemorrhage; in 16 of these, the hemorrhage was post partum, in 8 it was due to a separated placenta, in 5 to a placenta previa, and in 2 to a placenta accreta.

Of the 16 cases complicated by post-partum hemorrhage, the first was that of a multipara who had had five normal pregnancies. She began to bleed one hour after delivery of the placenta; the uterus was packed, and 2000 cc. of blood was administered. Ecchymotic spots developed all

over the body, and death occurred several hours post partum. In such a case the question of incompatibility always arises.

In the second case, that of a primipara who had had no prenatal care, bleeding occurred one week before delivery and had been preceded by a fall from a bicycle. Delivery was accomplished at home at about seven and a half months. Bleeding continued after delivery of the placenta; transfusion was not given, and death resulted one hour after delivery, before the patient could be transported to the hospital. In view of the fact that bleeding occurred at intervals after the patient's fall, it is possible that this fall in some way separated enough of the placenta to cause premature labor. The baby lived.

The third patient was a primipara who delivered herself spontaneously and began to bleed profusely eighteen hours post partum. Examination showed that the bleeding was coming from the vaginal mucous membrane. There was no bleeding from the uterus, which was hard, but there was a general oozing, which before death was complicated by bleeding from the rectum. Four transfusions were given. This was a very unusual case: the patient had syphilis and had received antisyphilitic therapy up to one month before delivery.

The fourth case was that of a multipara who was not seen until she was in labor. She was delivered at home, and the physician left shortly afterward, saying that everything was all right. The patient was left entirely alone, there being no one else in the house; a neighbor called in the evening and found her dead. This was undoubtedly a severe post-partum hemorrhage, although the death certificate attributed the fatality to "cardiac disease."

The fifth patient was a multipara who was delivered by simple low forceps. The placenta did not come away spontaneously, and one and a half hours after delivery profuse hemorrhage occurred. The placenta was removed manually shortly afterward, and a transfusion of 600 cc. of blood was given, in spite of which the patient died six hours later, undoubtedly from post-partum hemorrhage and shock. Additional transfusions might have averted this fatality.

The sixth case was that of a patient who had had intelligent prenatal care and in whom, after a spontaneous delivery, the uterus relaxed and did not regain normal tone. Death occurred two and a half hours after delivery.

The seventh case was that of a multipara who, following simultaneous delivery of the baby and placenta after a very strenuous labor, proceeded to flow freely and died in spite of the administration

of pituitary extract and ergotrate, and packing of the uterus. This death occurred at home; no transfusion was attempted.

The eighth patient was a primipara with a history of pulmonary tuberculosis who had a normal labor and began to bleed after delivery. The placenta was removed manually and is said to have been adherent. Five hundred cubic centimeters of blood was given, but death resulted in spite of this. It is possible that an additional transfusion should have been given and that a hysterectomy should have been considered.

The ninth patient, having had one previous uneventful pregnancy and convalescence, began to bleed two and a half hours after delivery, when she was found in a pool of blood. In spite of a transfusion, death occurred eight hours later. Massive hemorrhages do occur from atony of the uterus as late as two hours after delivery when there has been no previous unusual bleeding, but they are fortunately not common. Evidently much more blood than could be replaced by a single transfusion was lost before hemorrhage in this patient was recognized.

The tenth patient was a primipara who was delivered at home by mid-forceps after a seventy-two-hour labor. Hemorrhage followed delivery of the placenta and was checked by packing the uterus, but death occurred shortly. The patient was not given a transfusion. Such disasters are likelier to occur, of course, in a home than in a hospital, where the facilities for immediate transfusion should always be available.

The eleventh case was that of an elderly primipara in a hospital who, after delivery by low forceps following a normal labor, began to bleed after the birth of the placenta. The uterus and vagina were packed, but the bleeding continued. No transfusion was given, and the patient expired about five hours after delivery. There is hardly any excuse for a patient's dying of post-partum hemorrhage in a hospital.

It is difficult to ascertain the cause of hemorrhage in the twelfth case. Labor was induced in this patient for no apparent reason; after the cervix had become dilated to admit three fingers it was further dilated manually and the baby, which lived a few hours, delivered. The patient bled freely following delivery and went into shock, death occurring about one hour post partum. There is a possibility that the uterus was ruptured. This probably is a fatality attributable to bungling obstetrics.

In the thirteenth case, delivery was accomplished by low forceps in a patient who apparently had toxemia, and was followed by excessive post-partum hemorrhage. The vagina was packed and

the patient was transfused, but death occurred two hours after delivery. This patient had had ten previous spontaneous labors, and death was undoubtedly due to extensive post-partum hemorrhage.

The fourteenth patient was a multipara who had had three deliveries by cesarean section. When nearly at term she entered the hospital because of vaginal bleeding, and a cesarean section was immediately performed. Fifteen hours after delivery a profuse post-partum hemorrhage occurred; four transfusions were given, the uterus and the vagina were packed, but death occurred six hours later. One wonders why hysterectomy was not considered.

The fifteenth case was that of a patient on whom an elective cesarean was performed. Death occurred four and a half hours after the operation, and although the death certificate gives embolism as the probable cause of death, investigation leads one to infer that post-partum hemorrhage was the more reasonable diagnosis.

The sixteenth and last case in this group was a primipara who entered the hospital two hours after delivery. The placenta was extracted manually, presumably because of excessive bleeding, and the uterus was packed. In spite of this, bleeding continued through the pack, and hysterectomy was resorted to. Death occurred from peritonitis one week after delivery. Although this death was caused by peritonitis, the real reason for the operation was hemorrhage, and the case is so classified.

(To be concluded)

DEATHS

COCHRAN — WILLIAM J. COCHRAN, M.D., of Natick, died August 29. He was in his eighty-first year.

Dr. Cochran received his degree from Harvard Medical School in 1887. He was a member of the Massachusetts Medical Society and the American Medical Association and was formerly chairman of the board of health of Natick. He was a trustee of the Leonard Morse Hospital.

KEELEY — THOMAS H. KEELEY, M.D., of Monson, died August 28. He was in his forty-ninth year.

Dr. Keeley received his degree from the Middlesex University School of Medicine in 1923. He was a fellow of the Massachusetts Medical Society and the American Medical Association. He was on the staff of the Wing Memorial Hospital, Palmer.

WAR ACTIVITIES

CIVILIAN DEFENSE

INDUSTRIAL-HEALTH BROADCASTS

The two following series of industrial-health broadcasts will be given under the auspices of the Massachusetts Committee on Public Safety over the Boston stations indicated:

WMEY—Monday evenings, 10 10-10 15

- December 7 *Tuberculosis in Industry* Alton S Pope, M D
 December 14 *The Industrial Doctor* Louis R Daniels, M D
 December 21 *The Industrial Nurse* Catherine R Dempsey, R N
 December 28 *Industrial Rehabilitation* Daniel L. Lynch, M D

WNAC—Saturday afternoons, 12 30-12 35

- December 5 *Newer Chemical Hazards in Industry* John P Fahy, A B
 December 12 *Hazards to Health in Making Munitions* Irving R Tabershaw, M D
 December 19 *Industrial Skin Diseases* George E Morris, M D
 December 26 *Radium Poisoning among War Workers* W C L Hemeon, S M

The speakers in the first group are members of the Committee on Industrial Health of the Massachusetts Committee on Public Safety, those in the second are members of the staff of the Division of Occupational Hygiene, Massachusetts Department of Labor and Industries

INSTRUCTION IN THE DIAGNOSIS AND TREATMENT OF GAS CASUALTIES

Four of the scheduled dates (Springfield, Holyoke, Worcester and Beverly) for the six hour course covering the diagnosis and treatment of gas casualties, published in last week's issue of the *Journal*, were in error. The correct dates are as follows:

Springfield	December 15
Holyoke	December 18
Worcester	December 17
Beverly	Undecided

MISCELLANY

VENEREAL-DISEASE CONTROL AND THE PHARMACIST

The United States Public Health Service has recently issued a statement clarifying the role of the pharmacist from the public health viewpoint in the control of venereal disease and emphasizing his importance in the community as an educator, a personal influence and a citizen. Excerpts from the release are as follows:

The Pharmacist as an Educator

The pharmacist is an important influence in preventing the spread of venereal diseases, because persons who have these infections frequently go to him for advice or medicine. The pharmacist can make clear to the public that venereal diseases are dangerous, and that to act on the assumption that they are a trifling matter is more dangerous still. He can call on the state or local health department or the state pharmaceutical association for a supply of easy-to-read literature—attractive folders, leaflets, pamphlets and so forth—for free distribution to customers. He can avail himself of colorfully and effectively designed posters from his

state or local health department for display in his window or elsewhere in the drugstore. He can secure the ready advice and co-operation of such agencies as the Joint Committee of the American Pharmaceutical Association and the American Social Hygiene Association, the National Association of Retail Druggists and the United States Public Health Service. Education is a vital arm in the prevention and control of venereal diseases. The pharmacist is excellently placed to serve an educational role in the community.

The Pharmacist as a Personal Influence

The man who has (or thinks he has) a venereal disease and consults his pharmacist rather than a physician is usually laboring under the misconception that the disease is not serious enough to warrant a physician's attention, or that he can obtain just as effective treatment more cheaply by using a proprietary (patent) preparation sold without a prescription. In either case, he is asking the pharmacist, 'What should I do about my ailment?'

In such a situation, the very presence of a venereal-disease victim in a drugstore is fair testimony of the customer's strong personal confidence in the pharmacist. The pharmacist can easily enhance this confidence and add to his good will by exerting his personal influence to guide the customer on the proper course. He can point out the serious character of venereal diseases and the necessity of protecting the individual and the community. He can explain that it is always dangerous to treat oneself with a so-called 'remedy' or nostrum and to assume that one has been cured of syphilis or gonorrhea. He can refer customers who ask for such products to a reputable physician or to a clinic which provides diagnosis and treatment for venereal diseases. He can emphasize that the customer may have a different disease, requiring different treatment from the one he thinks he has, or that he may not even have any disease that a physician is trained to diagnose those diseases with the aid of physical examination and technical laboratory tests. The pharmacist who knows the dangers of venereal diseases and yet continues to diagnose them or to recommend or sell remedies for self treatment does more than violate a fundamental ethic of his profession. He becomes a contributor to whatever disastrous results may follow improper treatment or neglect.

The Pharmacist as a Citizen

As a citizen it behooves the pharmacist to help further the venereal disease control effort in his community by urging and supporting state and local legislation designed to lower the incidence of syphilis and gonorrhea. In some states, the pharmacist can enlist in the legislative campaigns sponsored by his own pharmaceutical organization, by the American Social Hygiene Association and by other health and civic groups, in promoting the enactment of premarital and prenatal laws for blood tests for syphilis. He should familiarize himself with all these activities. He can support legislation opposing advertising of fake cures by quack doctors, and prohibiting the sale of remedies for venereal diseases except by a physician's prescription. He can join the front line forces that are fighting for stricter laws and repressive measures against prostitution. As a citizen, he can insist on adequate treatment facilities for venereal-disease control in his community.

NOTE

The appointment of Dr. A. LeRoy Johnson, of New York City, as professor of clinical dentistry in the new Harvard School of Dental Medicine was recently announced.

gross misconduct in the practice of his profession as shown by his conviction in court.

H. QUIMBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

CORRESPONDENCE

AN OBJECTOR

To the Editor: About 5000 physicians of this state recently received a follow-up letter from the Massachusetts Medical Service (Blue Shield) urging them to sign up as members. These men had, of course, ignored the first invitation to join. They are told that 2300 of 7600 doctors in the state have signed. The letter ends as follows: "Sign today for a free profession charting its course in a revolutionary world. Will your boy be a free practitioner in America's tomorrow? Here are the agreements. There is the pen. Please sign."

Of all the high-power and pressure advertising over the radio designed to sell hair tonic or stock in a gold mine, none is more ridiculous or insulting to men of intelligence than this. This whole scheme has been put over on the 7000 men by the 600 who have an ax to grind. And then we are told that it is a plan worked out by the Society for the general good. Who is the Society? How many signed statements can they get from members that they were ever consulted or even approved of this plan? I have made it my business to question a cross section of the men at three hospitals with which I am connected and find none who approve. Even those who have signed state that they did so because they felt that they would be frozen out if they refused to do so. If this was a sincere plan for the betterment of all the doctors as well as the public, and not for just a few specialists who occupy the drivers' seats, some provision would have been made for payment of services to the general man. Why just the surgeon, with a sop to the obstetrician? I feel that advantage is being taken of the fact that hundreds of the younger and more active men are in the service, to force this scheme upon us.

May I strongly urge that all of you men who do not approve of this setup as at present planned, refrain from signing. Drop a line to the Massachusetts Medical Service and to the Society and tell them why. We all know that if the time ever comes that state medicine is to be forced upon us, that a plan such as this will not abort it. But in the meantime the specialist will be cashing in. They only have 2300 out of a possible 7600 members, and a great many of these will withdraw if given the opportunity. It is not too late. Fight back NOW!

C. EDWARD GREENE, M.D.

254 Washington Avenue
Chelsea, Massachusetts

* * *

Apropos of Dr. Greene's questions and musings, one cannot help but wonder if he has read the published reports of the meetings of the Council during the past two years and, if so, why he has remained silent so long. En.

DEPRIVATION OF LICENSE

To the Editor: At a meeting of the Board of Registration in Medicine held November 20, the Board voted to revoke the license of Dr. William P. Grovestein, Scituate, to practice medicine in this Commonwealth because of

BOOK REVIEWS

Lane Medical Lectures: The lymphatic system; its part in regulating composition and volume of tissue fluid. By Cecil K. Drinker, Sc.D., M.D. Stanford University Publications, University Series. Medical Sciences, Vol. IV, Number 2. 4°, cloth, 101 pp., with 29 illustrations. Stanford University, California: Stanford University Press, 1942. \$2.25 (\$1.50 paper).

In a readable and scholarly manner the author gives an authoritative account of the reasons "why mammals have lymphatics; why the lymphatic system has been slowly turned from a casually organized accessory of the blood circulation into a physiological entity, complementing this first system and joining with it in the task of keeping the composition and volume of the mammalian tissue fluid at a steady normal level."

In the opening chapter the author traces the evolution of the mammalian circulation in invertebrates and vertebrates and emphasizes the part that microchemical methods and micromanipulative and macromanipulative dissections play in answering the question why the lymphatic system appears and operates as it does. In keen literary style the author writes: "I have no objection to theories, but they are the cocktails not the roast beef of science." The next three chapters are concerned with the establishment of the capillary circulation, the appearance and elaboration of lymphatic vessels and the experimental evidence drawn from the heart and lungs to show the interdependence of the blood, tissue fluid and lymph. The final chapter deals with the role of the lymphatic system in wounds and in diffuse fibrosis of the lungs following the persistent inhalation of dust.

The book is well illustrated, with historical plates and figures, and an interesting bibliography is appended. Containing outstanding, up-to-date lectures, it should be in the personal library of all scientific investigators.

Anoxia: Its effect on the body. By Edward J. van Liere, M.D., Ph.D. 8°, cloth, 269 pp., with 17 illustrations and 15 tables. Chicago: The University of Chicago Press, 1942. \$3.00.

In clear language the author takes up systematically and in detail the effect of anoxia on all the known physiological processes of the body. Experimental facts and data are brought together to show the changes wrought by anoxia on the blood, on the heart and circulation and on the blood pressure and lymph and its effects on respiration, on the alimentary tract, on the endocrine glands and on urinary secretion. There are other chapters dealing with investigations concerning the influence of anoxia on metabolism, heat regulation, nutrition, water distribution and the nervous system. To achieve this task in a small book is something for which the author is to be congratulated. There are useful bibliographies at the end of the author's discussion of each system.

For those interested in aviation medicine and in air travel this book will make a strong appeal.

SKIN DISTURBANCES IN DIABETES MELLITUS: THEIR RELATION TO VITAMIN DEFICIENCIES*

ABRAHAM RUDY, M.D.,† AND RICHARD HOFFMANN, M.D.‡

BOSTON

SKIN disturbances in diabetes mellitus are very frequent. Commonest among them is pruritus, both general and local. The latter is especially observed around the genitalia, in fact, pruritus vulvae is frequent enough to be considered one of the cardinal symptoms of diabetes. Dermatitis is seen in the genital regions, in the intertriginous areas (submammary, inguinal and intergluteal) and in other parts of the body that are exposed to irritation of any kind. Fissures in the corners of the mouth and in the temporal angles of the eyes and changes in the nails and hair are frequently observed if carefully watched for. The skin in diabetic patients seems to be predisposed to pyogenic and mycotic infections. One thus finds, not infrequently, furuncles, carbuncles, pyoderma, hydrous adenitis axillaris, ecthyma and mycotic, especially monilia, infections of the skin. The frequency of these conditions in diabetes has prompted dermatologists to look for a disturbance in the carbohydrate metabolism whenever they are found. The literature is full of reports of this kind. Many of these patients have been subjected to glucose tolerance tests to discover a latent disturbance in the carbohydrate metabolism. In cases with normal glucose tolerance tests, skin sugar tests have been carried out.

There is a natural tendency to relate the sugar in the urine or blood or the various substances of the intermediary carbohydrate metabolism to most of the complications of diabetes. The increased blood sugar, as well as the sugar in the bodily excretions, such as sweat, saliva and urine, and in the skin itself, has been considered as a possible cause of the skin disturbances.

About five years ago one of us (A. R.) began a study of the various manifestations of vitamin deficiencies and their frequency in diabetes mellitus. It was soon found that skin lesions were not uncommon among our patients with such deficiencies. To evaluate the skin disturbances more carefully a dermatologist was assigned to the Diabetic Clinic of the Beth Israel Hospital. Our observations to date are that the skin manifestations in diabetes mellitus are frequently of the pellagrous type and that, on careful observation, signs of a deficiency of one or more components of the vitamin B complex, either before, during or after the discovery of the skin disease, can be revealed. At times there are also manifestations of a deficiency in other vitamins.

The following cases are presented to demonstrate that the skin disturbances in diabetes mellitus are most frequently due to a vitamin deficiency, especially that of nicotinic acid.

CASE REPORTS

CASE 1. A. K. (B. J. H. No. 1137A), a 41 year old woman, was discovered to have diabetes in 1934. She was usually careless with her diet, and took 70 units of insulin daily. In November, 1939, she developed skin lesions under the breasts and in the axillae. The skin of the submammary regions showed sharply defined, isolated and coalescent round and oval, slightly raised lesions, partly scaly, dry and red, from 5 to 30 mm in diameter, the axillary skin was red, dry, slightly indurated and partly peeling, the surrounding areas showed small, isolated, scaling lesions (Fig. 1). The urine showed sugar and the blood sugar was elevated.

The patient was started on 150 mg. nicotinic acid orally daily. After 2 weeks her skin condition showed a marked improvement. The nicotinic acid was then raised to 300 mg. daily. After 2 weeks the skin showed only pigmentation at the site of the subsiding lesions. By January, 1940, the skin was completely clear (Fig. 1) in spite of the fact that the diabetic condition remained uncontrolled. No local treatment was applied all this time. The nicotinic acid was then discontinued.

‡Instructor in medicine, Tufts College Medical School, associate visiting physician and chief of Diabetic Clinic, Beth Israel Hospital.

§Junior dermatologist at Beth Israel Hospital.

In February, 1941, the patient developed a severe pruritus vulvae with a vulvitis greatly disturbing her sleep. Her diabetes was still in the same poorly controlled condition. Because of a vaginal discharge she was referred to the Gynecological Clinic, where no explanation for the

and the pruritus vulvae cleared up in spite of the fact that the diabetes remained uncontrolled.

CASE 2. F. G. (B. I. H. No. 3593A), a 61-year-old woman, was found to have diabetes in 1929. She was on a diet

FIGURE 1. Case 1.

Skin under breasts before (left) and after (right) the administration of nicotinic acid.

pruritus vulvae was found. She was given vaginal douches and local treatment without relief. The pruritus vulvae gradually grew worse, and in June she developed for the second time lesions under the breasts similar to those found in 1939. The pruritus vulvae was still very severe

until 1932, when she was started on insulin. Pruritus vulvae developed in 1933 and cleared up without any special treatment. In June, 1938, she again developed pruritus vulvae, which disappeared after the insulin dosage was increased. The following August she presented an

FIGURE 2. Case 1.

Skin under breasts on recurrence (left) and subsequent disappearance (right) following the administration of nicotinamide.

and distressing. The patient was started on nicotinamide and received from 250 to 450 mg. orally daily and eighteen injections of 100-mg. doses parenterally in about 2 months. This resulted in an almost complete disappearance of the submammary skin lesions and of the vulvitis (Fig. 2).

Comment. In this case the skin lesions and the vulvitis represented manifestations of pellagra. They responded to nicotinic acid treatment and returned with its omission. Large doses and parenteral administration of nicotinamide were then necessary. It is worth noting that the skin

erosio interdigitalis on her right hand for about a week. In 1939 she developed a severe pruritus vulvae and an (Fig. 3) and other skin lesions. The skin in the groins and in the perianal region was deeply red and shiny in a sharply defined area. In the inguinal folds there were deep, bleeding fissures, while the skin of the labia minora and the mucous membrane of the vulva were red, slightly edematous and showed a whitish loosely adherent, spotty membrane. Under both breasts there were small, isolated, sharply defined reddish lesions somewhat elevated and slightly peeling. The skin of both cubital

regions, the inner side of the thighs and the lower part of the abdomen showed erythematopapulous eruptions.

corners of the mouth (perlèche) for a short time. In December, 1941, she complained of a severe dermatitis

FIGURE 3. Case 2.

The anal region before (left) and after (right) the administration of nicotinic acid.

Cultures from these areas revealed *Monilia albicans*. The skin condition did not respond to local treatment.

In October, 1939, the patient was started on daily doses

in the left ear canal. The skin of the meatus auditorius was red, dry, scaly and indurated. She was given nicotinic acid up to 300 mg. daily for several weeks without

FIGURE 4. Case 3.

The palmar skin and nails before (upper) and after (lower) the administration of nicotinic acid and vitamin B complex.

of 150 mg. of nicotinic acid orally. This was continued until February, 1940, when the pruritus vulvae and ani completely disappeared in spite of the fact that the diabetic condition remained unchanged (Fig. 3). In March the pruritus vulvae recurred and cleared again with nicotinic acid. In 1941 the patient showed fissures in the

local treatment and the dermatitis in the ear completely cleared up.

Comment. The interdigital, vulvar, anal and ear lesions in this case represented pellagra. They responded to the treatment with nicotinic acid. Here again the skin improved, although the diabetes remained unchanged. This

case illustrates that the skin lesions do not always occur simultaneously and therefore are frequently incorrectly diagnosed.

CASE 3. M. F. (B. I. H. No. 57214A), a 70-year-old woman, was seen for the first time in July, 1939, when she was admitted to the wards because of a generalized

trol of the diabetes by diet and very small doses of insulin, and with the administration of vitamin B complex, vitamin B₁ parenterally and nicotinic acid orally, 300 mg daily, the skin condition was much improved in a very short time (Fig. 4). No local treatment was used. The mental and general condition also improved. The vivid red in the genital and perianal regions changed to a

FIGURE 5. Case 4.

The ankle before (left) and after (right) treatment with nicotinic acid.

dermatitis. Diabetes mellitus was discovered on admission. There had been a loss of weight for about 2 years. On examination the tongue was beefy. The skin of both palms was dry, macerated, thickened, scaly and cracked. The interdigital folds were macerated and fissured. The skin of the dorsum of the hands was rough, red, dry, indurated and slightly peeling. The skin on both knees and elbows was dry, rough and red. The fingernails consisted of soft lamellar masses (Fig. 4). The skin

reddish, dark-brown discoloration, which gradually subsided.

A few months later the patient developed an acute psychosis with amnesia for certain happenings and hallucinations. She became violent and was admitted to a hospital for chronic patients. In spite of large doses (1000 mg. daily) of nicotinic acid, she succumbed in a psychotic state.

Comment. This patient presented a classic picture of acute diabetes mellitus with pellagra. The skin manifestations responded well to treatment with nicotinic acid, while the psychosis did not.

FIGURE 6. Case 5.

This photograph shows the smooth tongue.

of the genital, inguinal and perianal regions was dry, indurated, red and rough.

The neurologic examination showed absent abdominal reflexes and knee and ankle jerks. The arm reflexes were present. There was a positive Hoffmann's sign on the right and a grasp reflex. The mental picture was somewhat similar to Korsakoff's psychosis. With the con-

CASE 4. R. N. (B. I. H. No. 33806A), a 46-year-old woman, was found to have diabetes mellitus in 1934, with an acute pruritus vulvae, which cleared up with the control of the diabetes. She was not seen for 4 years. On her return to the clinic in November, 1939, she admitted being careless with her diet. She complained of an itching skin eruption on the ears, under the breasts and in the pubic and sacral regions of 3 years' duration. The skin of both ears was indurated, red, dry and partly covered with slightly adherent whitish scales (Fig. 5). The retroauricular and intra-auricular regions showed similar skin changes in sharply defined areas with oozing, partly crusty, deep fissures. The skin under the breasts showed slightly scaly, isolated lesions on a somewhat indurated and slightly erythematous base. A few similar lesions were found in the pubic, intergluteal and sacral regions. The skin in the regions of the olecranon and the patellas was rough, somewhat scaly and indurated. The lips were dry. There were fissures with some induration in the corners of the mouth.

The patient was given a diet and insulin. In addition, lanolin was applied locally. In 1 month the diabetes was under control. The skin of the ears was paler, still dry

and indurated, with a few scales. The retroauricular region still showed induration, scaliness and fissures. The skin under the breasts and in the pubic and sacral regions showed no improvement. The patient was started on 200 mg of nicotinic acid orally daily, without any local treatment. The diet and insulin dosage remained un-

changed. The patient showed a beefy tongue, perleche and a dry, shiny and somewhat atrophic skin with areas of depigmentation and hyperpigmentation. The skin on the back showed a carbuncle and numerous superficial ulcerations, surrounded by indurated brownish red dry and scaly areas. There was also a marked vulvitis. The blood pressure was

FIGURE 7 Case 5

Feet and lower legs showing dry shiny atrophic skin

changed. Within 2 weeks all the skin manifestations including the fissures in the corners of the mouth, showed improvement. Two weeks later the skin almost completely cleared up. The patient was continued on 150 mg nicotinic acid orally daily for 2 more weeks. The skin remained clear (Fig 5). This time, however, she returned with symptoms of a peripheral neuritis, namely, pain and numbness in the hands and fingers and a tingling sensation in both legs. The nicotinic acid was omitted, and she was started on yeast tablets.

Comment This patient showed the skin manifestations of an atypical pellagra. She presented symptoms of a deficiency of the various components of the vitamin B complex. It is possible that the neuritis was precipitated by the intensive nicotinic acid treatment without the use of the entire vitamin B complex. It is generally believed that the administration of large doses of one vitamin increases the demand for the other vitamins.

CASE 5 B F (B I H No 48848), a 39-year-old woman, was admitted to the surgical wards because of a carbuncle on the back. She gave a history of diabetes mellitus of 6 years duration, controlled by diet and insulin. The urine was sugar free most of the time. She was irregular with her meals, and frequently omitted her lunches. For at least 4 years she had complained of attacks of pruritus vulvae, dysuria and generalized pruritus, in spite of the absence of sugar pus or bacteria in the urine.

The patient stated that her skin had been very shiny and paperlike for about 2 years. On examination she

showed a beefy tongue, perleche and a dry, shiny and somewhat atrophic skin with areas of depigmentation and hyperpigmentation. The skin on the back showed a carbuncle and numerous superficial ulcerations, surrounded by indurated brownish red dry and scaly areas. There was also a marked vulvitis. The blood pressure was

140/80. The urine was sugar free with large traces of albumin. The carbuncle was incised. In addition to the diet and insulin, the patient was given vitamin B complex and 300 mg of nicotinic acid orally daily and also vitamin B₁ intramuscularly. She was discharged improved 9 days after admission. In August, 1940 the patient returned to the medical wards. She had developed a severe hypertension in the meantime and 2 weeks before the second admission began to have severe attacks of vomiting and dizziness. Because of the vomiting she had limited her diet and eaten very little. She continued, however, to take her insulin. On examination she showed a blood pressure of 260/130. The fundi showed marked edema of the disks, with old and fresh hemorrhages and cottonlike exudates. The heart was enlarged to the left. There were numerous rales at the right base, with dullness to flatness. The tongue was red and smooth (Fig 6). The skin showed a marked progression in the changes described on her previous admission (Fig 7).

Laboratory data revealed no anemia, total protein 4.5 gm per 100 cc, nonprotein nitrogen 35 mg per 100 cc, circulation time 30 seconds, basal metabolic rate -4 per cent, spinal fluid protein 51 mg per 100 cc, and a negative gastrointestinal series. The urine showed large traces of albumin.

In addition to the multiple vitamin deficiency state a diagnosis of intercapillary glomerulosclerosis was made. After discharge the patient developed generalized edema and received mercurial diuretics regularly from her family physician. In November, 1940, she was readmitted in a

comatose state. Her condition grew rapidly worse, the temperature rose to 104°F., and she expired on the 6th hospital day.

Comment. This case showed definite signs of pellagra, such as the beefy tongue, perleche and vulvitis. Whether the skin changes were due to the vitamin B deficiency alone or also to a vitamin A deficiency, we are still unprepared to say. In this case also the pruritus vulvae was present for many years in the absence of glycosuria.

DISCUSSION

In addition to the cases described above we have seen many more diabetic patients with similar more or less pronounced skin eruptions. A review of the literature to date shows that the entire subject is unsettled and somewhat confused. There is still a widespread belief that the skin lesions in diabetes mellitus are in some way related to the disturbed carbohydrate metabolism, although Goldsmith¹ and Rost² definitely expressed their doubt that certain groups of skin diseases are regularly connected with hyperglycemia. In 1931, Rudy³ discussed the relation of the skin to the carbohydrate metabolism and reviewed the literature. At that time very little was known about the skin manifestations. In addition to the glycosuria and hyperglycemia, the increased sugar in the sweat⁴ and in the skin^{5,6} were considered as possible precipitating causes of the skin lesions. Hesselstine,⁷ who made a special study of vulvovaginitis in diabetic patients, claims that "synthetic glycosuria" does not produce vulvitis or pruritus. He believes, however, that glycosuria provides a good medium for fungus infections. Goldsmith¹ states that the diabetic skin is more easily infected with monilia than normal skin, but admits that the severity of the infection does not coincide with the degrees of hyperglycemia. Greenwood and Rockwood⁸ believe that in diabetic patients the monilia infections affect the mucous membrane of the vulva and may extend to the skin, whereas in nondiabetics it is commoner in the groins and axillas and under the breasts. Greenwood⁹ divides pruritus ani in diabetic patients into three types: Type 1 shows a definite infection of the skin with bacteria; Type 2 shows an infection with fungi; and Type 3 has no change in the skin. His treatment varies but is local. Lamb and Keltz¹⁰ in 1941, in a paper on skin manifestations in diabetes mellitus, state that the decreased resistance of the uncontrolled diabetic patient to infections of the skin is still unexplained but that it is definitely related to the control of the diabetes. In 1940 Rudy¹¹ stated that skin manifestations of the pellagrous type are not uncommon in diabetes mellitus.

The skin of some of the diabetic patients is not unlike that of the pellagrins. It shows an increased vulnerability to any kind of external irritation (rubbing or other mechanical or chemical trauma,

perspiration, heat or sunlight) and to infections, especially those due to monilia. We have shown in our cases that vulvitis as well as pruritus vulvae and ani in diabetes are proved signs of pellagra and are due to a nicotinic acid deficiency. It is interesting that in 1908 Nicholas and Massia¹² gave a description of pellagrous vulvitis and perivulvitis that coincides exactly with our observations in diabetic patients.

As a result of old textbook descriptions of the skin lesions in pellagra, there is still a tendency to relate the diagnosis of pellagra with the classic picture in which the face, the neck (*collier de Casal*) and the back of the hands are pointed out as the typical localization, as opposed to atypical localization in other parts of the body.

Exposure to sunlight was considered as one of the main etiologic factors of the pellagrous skin manifestations. Today it is known that exposure to sunlight is only one of the irritants and not at all one of the most frequent.

In the same way we cannot always expect to find the fully developed picture of pellagra, consisting of dermatitis, glossitis, gastrointestinal disturbances and mental changes. The skin lesions, like some of the other manifestations, may be missing or may be so mild and in such a localization that they can be completely overlooked. Since dermatitis was formerly the most important diagnostic finding in pellagra, in its absence cases were diagnosed "pellagra sine pellagra." The localization of the skin lesions in pellagra depends on the site of the exposure to irritation of any kind. One may find skin eruptions in any part of the body in lesser or in greater degrees, and they should be looked for in areas that are exposed to irritation. Wherever a single lesion suggesting pellagra is observed, a careful examination frequently reveals other skin lesions or some other signs of pellagra, such as glossitis, pruritus vulvae or gastrointestinal or mental disturbances.

Most of the manifestations of pellagra respond to treatment with nicotinic acid. Since nicotinic acid is a component of the vitamin B complex, a careful search often discloses that signs of a deficiency in the other components, such as riboflavin and thiamine chloride, have preceded or are present, or such lesions may be expected to follow.

The morphology of the skin lesions depends on their localization, the thickness of the involved horny layer, the quantity and quality of the local irritation and the severity and duration of the deficiency. The most frequent manifestation is a vivid, more or less indurated erythema, which is characterized by a violaceous or brownish color and a definite shine on the surface. Fine lamellar peeling or psoriasiform scaliness, more or less deep ridging of the papillary lines and fissuring, edema,

Loss of weight, infections, gastrointestinal disturbances, acidosis, overindulgence in alcohol and operations may act as precipitating factors in the development of the deficiency symptoms in diabetes mellitus.

CONCLUSIONS

Skin disturbances are common in diabetes mellitus.

They are not related to the glycosuria or hyperglycemia but are due to an increased vulnerability of the skin as a result of a deficiency in the components of the vitamin B complex, especially nicotinic acid.

Furuncles, carbuncles and other pyogenous as well as mycotic infections may occur alone or combined as a result of this vulnerability.

Pellagrous dermatitis in diabetes is especially frequent and is often diagnosed and treated as psoriasis vulgaris.

Pruritus vulvae and ani in diabetes are a manifestation of pellagra and respond to treatment with nicotinic acid.

A careful history and physical examination in these cases will invariably disclose manifestations or signs of a multiple vitamin deficiency, a beefy or smooth tongue, cheilosis and gastrointestinal, genitourinary, neurological, mental and other disturbances. These signs in the various systems of the body do not always occur simultaneously. They may precede or follow the skin disturbances.

The skin lesions may improve, remain unchanged or even become aggravated with the control of the diabetes by diet, with or without insulin. They always respond to treatment with nicotinic acid. The monilia infections clear up without local treatment. A complete cure from nicotinic acid treatment may take from a few days to several months. The more stubborn cases require fairly large doses parenterally as well as orally.

Since the vitamin deficiency is frequently multiple the entire vitamin B complex should be administered in addition to the nicotinic acid, which can also be given in the form of nicotinamide.

Recurrences are not uncommon if the underlying cause is not or cannot be removed. Infections, gastrointestinal disturbances and acute upsets in the carbohydrate metabolism predispose to recurrences. The administration of vitamin B complex may therefore become a permanent necessity for some patients.

MESENTERIC THROMBOSIS IN MENTALLY ILL PATIENTS*

CONRAD BELL, M.D.,† WILLIAM CORWIN, M.D.,‡ O CAR J MARCIL, M.D.,§
AND ELVIN V. SEMRAD, M.D.¶

WALTHAM, MASSACHUSETTS

THE diagnosis of occlusion of the mesenteric circulation by venous thrombosis or embolism is often difficult and is usually made at operation or autopsy. The problem becomes somewhat more difficult when a patient suffering a mental illness, handicapped in his communicability, suffers a mesenteric thrombosis or embolism. We have had opportunity to study 5 cases in the last five years, 2 verified by autopsy, 1 by operation and 2 by clinical methods. Of the latter, one patient died and we were unable to perform an autopsy, and the other recovered without operation. As the last 2 cases mentioned are open to considerable question because of lack of verification, we shall emphasize the 3 cases that we had a chance to verify.

Pollok¹ emphasized the importance of this disorder because of the severity of its effects rather than because of its frequency; he stated that the literature up to 1937 contained reports of about 500 cases, many of which were collected by Galvin.²

There are certain points that suggest the diagnosis. Although the disease may occur at any age, even in childhood,⁴ it is more commonly a disease of later life. It is usually associated with some disease of the circulatory system, such as endocarditis, atheroma of the aorta or arteriosclerosis, and there may be a history of embolic phenomena in other parts of the body before the onset of abdominal symptoms, or simultaneously with them. It has occurred in patients with chronic diabetes.

The classic signs and symptoms are severe abdominal pain (generalized over the abdomen, constant or in exacerbations), vomiting, melena and distention of the abdomen with tympanites and at times a shifting dullness in the flanks. Blood was present in 41 per cent of the cases reported by Jackson et al.⁵ When the process of infarction involves the upper intestines, a vomiting of blood has been reported. The patient may show signs of collapse, with a fall in body temperature. A low pulse rate is sometimes found at the onset of the attack. The leukocyte count is elevated, in the series of 92 cases collected by Meyer⁶ the

count in all but 3 averaged 18,000, the highest being 45,000. Dunphy and Zollinger⁷ stressed the fact that although the clinical picture varied considerably, several important features could be recognized in such cases. First, it was observed that regardless of the duration of the attack, the clinical picture was not typical of any of the common surgical emergencies. The localized tenderness of appendicitis, the rigidity of perforated ulcer, the visible peristalsis and early distention of acute intestinal obstruction were not present. It was not the problem of a mistaken diagnosis but of no diagnosis. However, the patients were obviously ill from an abdominal lesion that simulated obstruction. Secondly, the character of the pain in each case was out of proportion to the clinical picture. This was so striking in one case that the staff favored a diagnosis of hysteria. Another significant characteristic of the pain was its persistence after the usual measures for its relief such as, small doses of morphine, enemas and continuous gastric lavage, had been instituted. Thirdly, the only constant physical finding was abdominal tenderness, more or less generalized, with rebound tenderness referred to the point of pressure. Fourthly, all the patients had a relatively high leukocytosis, a high or mounting pulse rate and a temperature that was normal or only slightly elevated. Finally, it was evident in each case that there was a gastrointestinal disturbance, but this was not manifested in any constant manner. Difficulty in moving the bowels without evidence of complete obstruction was seen in all cases. Vomiting was variable and bloody diarrhea did not occur. Rapidly progressing shock was seen in 1 case.

McVier⁸ in a series of 9 cases found 3 in which the circulation was occluded in other ways than by mesenteric thrombosis.

Clinical manifestations are quite varied. Many cases cause no symptoms suggesting mesenteric thrombosis and the condition is found only at autopsy.⁶ Some run a chronic and some an acute course.⁷ In the larger, acute group there may be a sudden onset of colicky pain characteristic of obstruction, often at a time when the patient is in good health. Death usually follows in a few days or even hours. The pain is usually generalized over the abdomen; it may be constant and extremely severe, although not infrequently there

are exacerbations with comparative comfort between attacks.

Brown⁹ stated that 772 cases of both arterial and venous occlusion had been reported in the literature. He studied 104 cases of venous mesenteric occlusion. Other reports were reviewed¹⁰⁻²¹ to compare the problem as it exists in patients in general hospitals with that of those suffering from mental illness.

The group of cases that run a chronic course is smaller; onset is insidious, and they may go on to a spontaneous cure. Cases in the literature²²⁻²⁹ have been reviewed in comparison with our own.

In our cases a differential diagnosis not usually mentioned in the literature arose, that is, the evaluation of the problem of head injury or intracranial disease. One of Abrams's³³ cases is suggestive of possible intracranial complications, which were not verified at autopsy. This patient (Case F), aged thirty-two, suffered rheumatic heart disease with fibrillation, and two weeks before the discovery of mesenteric thrombosis was seized suddenly with a severe pain on the left side of the head, after exertion caused by moving heavy objects. It lasted five days and was diagnosed as an embolus in a silent area of the brain, in the absence of neurologic findings. Feeling better for a time, the patient got up to go to the bathroom, and while at stool was suddenly seized with a violent attack of pain in the midabdomen, which at autopsy was proved to have been due to mesenteric thrombosis.

CASE REPORTS

CASE 1. J. F. D., a 58-year-old fireman, was diagnosed as having psychosis associated with organic changes of the nervous system and paralysis agitans.

The paternal grandmother was said to have had mental symptoms following the menopause. The maternal grandfather died of diabetes.

Little was known about the patient's childhood diseases. A sister believed that he had typhoid fever when he was 8 years of age. She stated that in 1932 or 1933 he suffered from two "shocks" but continued working for nearly a year following them. In 1933 he began to have difficulty with his eyesight and was gradually relieved of most of his duties because of physical disability. At this time he walked in a stooped manner, with the arms held in an "ape-like," semiflexed manner. His memory began to fail, and he made mistakes in his work. Neurologic examination in October, 1933, yielded the diagnosis of paralysis agitans, probably on an arteriosclerotic basis. About this time he began to show more prominent mental symptoms, becoming restless, emotionally unstable, confused and incontinent. He was admitted to the hospital in July, 1935.

In the evening of November 6, 1937, the patient vomited a small amount of undigested food about 1 hour after supper. He slept all night. At 7:35 the next morning he fell out of bed, but was not unconscious. Contusions of the left eye and of the right frontoparietal region were noted. The temperature, pulse and respirations were nor-

mal. On November 8 the patient vomited twice after supper. The temperature was 99°F., the pulse 98, and the respirations 22. A soapsuds enema was given, with good results. He vomited large amounts of greenish fluid twice during the evening. On the morning of November 9 the patient vomited thick, viscous, brownish coffee-grounds material; the vomiting was described as projectile. The color was poor, the pulse was weak, and the patient seemed to be in a state of semicollapse. The blood pressure was 90/0. He was incontinent. His general condition improved after a stimulant. A spinal-fluid examination showed a pressure of 50 mm. (water), a protein of 70 mg. per 100 cc., a sugar of 120 mg., a chloride of 837 mg. and a red-cell count of 1000. At 1 o'clock the pulse was very weak and irregular; the patient was incontinent and vomited again a small amount of fluid. There was some twitching of the arms and legs. The respirations were labored and irregular, at times being recorded as low as 4 per minute. The skin was warm. He continued to be nauseated and attempted to vomit. A neurologic examination the evening of the same day was reported as follows:

The patient is pale, emaciated and semicomatose. He resists and groans whenever attempts at examination are made. The pupils are equal, of medium size, and react to light. The eyegrounds show congestion of the retinal vessels. The disks are congested, but the edges are clear. No papilledema is noted. There is no exudate. There is slight weakness in the left lower face. The patient lies on his right side in a jackknife position, with the arms crossed on the abdomen. Attempts to extend the arms and legs meet with severe resistance. The abdomen is rigid and boardlike. Palpation of the abdomen is electively painful. There is no paralysis of voluntary movements in the upper or lower extremities. The tendon reflexes are blocked by voluntary flexion and spasm. The plantar reflexes are flexor bilaterally. The spinal-fluid findings appear to be rather baffling. There are no neurologic signs pointing to intracranial injury, but there is a left-lower facial weakness, which may be related to the history of paralysis agitans of some years' duration. Profuse vomiting of brownish, viscous material, pain and abdominal rigidity, with signs of collapse, make it necessary to eliminate an abdominal condition before considering intracranial injury or cerebral accident.

A surgical consultation was held and it was found that the patient was practically moribund. The recti muscles were very spastic but the sides of the abdomen were comparatively soft. At 9:15 p.m. the patient suddenly grew weaker. Coarse, moist rales were present in both lung fields. The temperature was 101.8°F.; the white-cell count was 17,450. He was pronounced dead at 9:55 p.m.

Autopsy. The stomach appeared enormously dilated. There were numerous bloody retroperitoneal adhesions beginning at the sigmoid, following up the descending colon and extending to the lower edge of the left kidney. Over the sigmoid the color was greenish, indicating beginning gangrene. The transverse and descending portions of the colon were filled with hard masses. The vessels of the mesentery were excessively engorged. The duodenum was quite distended, and there was no constriction therein or at the pylorus. Below the pylorus was a tear in the duodenum about 1.0 cm. in length. The stomach contained about 1000 cc. of greenish fluid, with some heavy, solid food mixed with it. The mucous membrane of the

stomach was moderately injected. The brain showed no evidence of subdural or intracranial hemorrhage. Diagnosis: mesenteric thrombosis, rupture of duodenum, lobar pneumonia.

CASE 2 B F M, a 61 year-old garage mechanic, was diagnosed as having manic depressive, depressed, psychosis.

At the age of 7 the patient had an attack of meningitis, from which he made a good recovery. An appendectomy was performed in 1905, following which he was ill for many months. In 1911 he was in bed for 11 weeks, suffering from a duodenal ulcer, accompanied by severe hemorrhages. In 1920 he had a severe attack of mumps but suffered no serious sequela. Since 1911 he had had periodic attacks of constipation, nausea and vomiting probably related to his ulcer, although cancer was suspected. An x ray examination in 1932 showed the stomach to be normal but the first part of the duodenum was continually deformed by a large ulcer. While in another mental hospital between the years 1932 and 1937, an exact date unknown, he suffered at one time from a severe hemorrhage and was seriously ill. On May 6, 1937, he complained of abdominal pain, which improved following a Sippy regime. X ray examination of the gastrointestinal tract at this time revealed a deformity of the duodenum believed to be an old ulcer sclerosis.

On January 5, 1938, at 11:45 p.m., the patient attempted to get out of bed, became dizzy, and fell backward, apparently striking his head on the wall. He was unconscious for 5 minutes, during which time the attendant was unable to get the radial pulse. Later, he stated that he felt very weak, confused and dizzy. There was no external evidence of injury to his head. The temperature was 99.4°F, the pulse 114 and of good quality, and the respirations 20. He slept fairly well during the rest of the night, but the next morning he still complained of being somewhat dizzy and appeared weak and somewhat drowsy. The blood pressure was 104/52. He ate his breakfast and noon meal without difficulty. The next morning (January 6), the temperature was 99.4°F (rectal), the pulse 100, and the respirations 20. The patient stated at this time that he had been vomiting off and on for weeks, with pain in the abdomen radiating to the back. At noon the temperature was 100.2°F, the pulse 124, and the respirations 22. A neurologic examination at three o'clock revealed the left knee jerk as slightly more active than the right, and the right ankle jerk as slightly more active than the left. Bilateral Babinski signs were present, with some impairment of position in the toes. The eyegrounds revealed retinal sclerosis. A preliminary diagnosis suggested vascular accident, on the basis of cerebral arteriosclerosis, vascular thrombosis and intra-abdominal bleeding. At 3:15 p.m., the patient complained of severe abdominal pain. He became cold and clammy, moaned and complained of severe pain in the back, and perspired profusely. The right upper quadrant of the abdomen was tender, with spasm. The blood pressure was 58/0, and the pulse 140. The red cell count was 2,860,000, with 49 per cent hemoglobin, and the white-cell count was 9800. Surgical consultation yielded the following note:

Patient in collapse, cyanotic, with poor pulse. Abdominal examination shows a scaphoid abdomen, with no marked spasm. A small tumor mass is felt to the left of the umbilicus, which is not movable. I think this is a case of hemorrhage in the bowel, possibly from the duodenal ulcer. Advise transfusion 250 cc., today, repeat tomorrow.

The patient was able to locate the pain as being centered in the abdomen and also as present over the inferior angle of the right scapula. His condition rapidly became poorer, and he failed to react to stimulants and to intra-venous saline and glucose. He was being prepared for transfusion when he expired, at 6:53 p.m. Shortly before death the respirations became Cheyne-Stokes in nature. He remained conscious until a few minutes before death.

Autopsy. The abdominal organs in situ presented a striking appearance in their diffuse, red, wine-like color. The omentum was thin and reddish, with engorgement of the veins. When it was reflected, the transverse colon and sigmoid appeared immensely distended and had the color and appearance of a ripe eggplant. The deep peritoneal cavity contained free, port wine-colored fluid. The surfaces of the visceral and the parietal peritoneum were smooth and glistening. There were no adhesions or exudate anywhere except for a thick, fibrous adhesion of a fringe of omentum to the parietal peritoneum in the right iliac fossa. There was no pus. The congestion of the large intestine was present throughout its distal iliac portion but showed only in spots and patches in the higher segments of the small intestine. The appendix was absent. The stomach had a whitish color and appeared to be distended with a large amount of fluid. The liver was smooth, pale brown and homogeneous in consistence. The gall bladder was distended with liquid contents. The stomach was filled with a large amount of pinkish black liquid and many spongelike lumps, apparently clotted blood. The gastric mucosa was pale and showed no erosions, masses or ulcerations in its wall. The duodenum and the proximal portion of the jejunum were filled with greenish black material. Proceeding distally, there was increasing congestion of the intestinal mucosa, and in the ileum it appeared as if lined with a thick mass resembling currant jelly, red wine in color. In the proximal portion of the ileum the contents of the intestine were frankly bloody. The mucosa was deep purplish red. The cecum was filled with what appeared to be thick, coagulated blood. The contents of the colon was fresh blood. The sigmoid was filled with soft fecal masses, black and homogeneous in color. There was no evidence of intracranial injury. Diagnosis: mesenteric thrombosis, associated with intestinal hemorrhage.

CASE 3 M M, a 59-year-old bartender, was diagnosed as having psychosis with cerebral arteriosclerosis.

The patient was born in Italy and came to this country at the age of 2½. He studied music in his early youth. Later he worked as a bartender, until prohibition. He was temperate in his habits. Commitment to a mental hospital occurred in August, 1930, as a result of irritability, fatigue and emotional instability.

In 1926, it was discovered that the patient had diabetes mellitus, and he was treated by means of a diet. Through out his stay in various hospitals he was under treatment for this condition. This was controlled without difficulty by means of diet and insulin. He also suffered from arteriosclerosis, hypertensive heart disease and chronic nephritis. In 1935 and 1936, he suffered from occasional attacks of dizziness and weakness, at times accompanied by convulsive manifestations. In 1937, it was noted that he had a partial hemiplegia of the left arm and left leg.

On December 25, 1937, about 9:30 p.m., the patient vomited large amounts of food. The temperature was 100.1°, the pulse 90, and the respirations 20. He did not complain, and examination at that time revealed no acute signs. He slept quite well in long nap and in the

morning the temperature, pulse and respirations were normal. Urine examination revealed a brown reduction, and he was given 20 units of insulin. He ate his breakfast, and about 10 o'clock complained of needing an enema, which was given, with very good results. At 12 o'clock he again vomited a large amount of yellow fluid containing sizable pieces of food. At this time he was moaning and groaning considerably and tossing about, and complained of severe abdominal pain. There were tenderness and spasm in the right and left lower quadrants. Although the patient had previously urinated without difficulty, he stated that if he could only pass his urine he would be relieved. He was catheterized and 150 cc. of urine was obtained. A test at this time showed a yellowish-green reduction. About 1:30 a.m. the patient again vomited large amounts of undigested food. The white-cell count was 18,000, with 88 per cent polymorphonuclears. He seemed relieved of pain following this attack of vomiting and stated that he was more comfortable. Another physical examination revealed persistence of tenderness and spasm in the right lower quadrant. A surgical consultation was held and a diagnosis of acute appendicitis was made.

Operation was performed shortly before 5 o'clock. When the abdomen was opened through a right-rectus incision, a large amount of yellowish, clear, free fluid was expressed. Exploration revealed 60 cm. of the small intestine to be quite bluish in color, with several areas of dark-blue spots. It was noted during exploration that several dark-blue spots were growing progressively larger and that the bowel was becoming more discolored. A large area of venous thrombosis in the mesentery of the small intestine was found. The mesentery bled freely and tore easily. There were large, firm, movable fecal masses in the intestines. The appendix was found to be normal. During the operation the pulse rose to 180, became rapid and irregular, and coramin had to be given. Because of the poor condition of the patient, it was found advisable to terminate the operation without resecting the intestine. The abdomen was closed in layers, with a Penrose drain. His condition remained poor although the pulse improved following the use of stimulants.

On December 27, the patient's condition was found to be very poor. He was moaning, apparently in pain, and quite restless. The temperature was 102.4°F., the pulse 144, and the respirations 16. At times the patient was cyanotic and the blood pressure could not be measured. He continued to vomit frequently. Respiration was at times labored and difficult, and the pulse continued to be irregular. The white-cell count was 13,250, with 81 per cent polymorphonuclears. On December 28, the condition was essentially unchanged. The temperature was elevated; the pulse was rapid, thready and of poor quality. The systolic blood pressure could not be obtained. The color was poor. The skin was cold and clammy, and the patient complained of abdominal cramps. On December 29, he seemed to be more comfortable, although he still continued to moan at intervals. There was no distention. He did not tolerate nourishment very well, vomiting occasionally. On the morning of December 30, the temperature was 101.4°F., the pulse 108, and the respirations 20. He continued to have pain but seemed to be in better physical condition. The pulse was of fairly good quality and the patient seemed to be brighter mentally. A white-cell count on the 29th had been 8950, with 83 per cent polymorphonuclears. On the 30th it was 7850, with 73 per cent polymorphonuclears. The urine showed moderate traces of albumin and sugar, with granular and hyaline casts. During the day of December 31, the tempera-

ture rose to 103.6°F., the pulse to 136, and the respirations to 22. The patient did not complain of severe pain, and the pulse was of fairly good quality, although rapid. On the morning of January 1, the temperature was 103.4°F., the pulse 126, and the respirations 26. The patient appeared to be weaker and seemed to be in more pain. He was not very responsive. The pulse at this time was weak and thready. During the day the temperature continued to rise. At 7 p.m. it was 105.4°F., with a pulse of 144 and respirations of 32. The patient was cold and clammy, was quite weak, and the pulse was rapid and thready. He did not respond and appeared moribund. On the morning of January 2, the temperature was 106.4°F., the pulse 160, and the respirations 44. The patient failed to react to stimulants and rapidly grew weaker, and finally comatose. The respirations were shallow and rapid. The extremities were cyanotic. He continued to vomit and finally expired at 7:35 p.m.

Permission for autopsy was not obtained. Diagnoses: diabetes mellitus; mesenteric thrombosis; peritonitis; cardiac arteriosclerosis.

DISCUSSION

The onset of 2 of our cases was with vomiting that was not associated with symptoms suggesting an acute surgical condition of the abdomen, but in a few hours the symptomatology became that of an acute abdominal emergency. In mental patients, vomiting is frequently associated with constipation and the symptoms disappear after enemas.

Two cases presented the differential problem of possible head injury, and in one case the diagnosis was difficult because of the spinal-fluid studies. In such cases, however, a review of past examinations and reports helps one arrive at a decision concerning the neurologic findings added to the clinical picture that may be indicative of head injury.

Severe abdominal pain was present in each case, not particularly abrupt in onset but severe and generalized. Although the patient in Case 1 did not complain of the pain it was evidently quite severe. The vomiting at first was productive of gastric contents, in one case of several hours' duration and in another becoming coffee-grounds in character as vomiting continued. Distention did not seem to be much of a problem in these cases. Bleeding into the intestine was suggested at least in 2 of the cases. (One of us [C. B.] studied a case in a nonpsychotic patient, which was verified by operation. In this case there was melena during the course of the disease.) Shock symptoms were present in all cases. The number of leukocytes was not higher than that usually associated with abdominal emergencies.

The fact that the clinical picture was not typical of any of the common surgical emergencies is important. The past medical histories yielded some information of associated diseases but were not too helpful in making a diagnosis of mesenteric thrombosis. The fact that the patients became so

extremely sick should have suggested the possibility of mesenteric thrombosis.

SUMMARY

Three cases of proved mesenteric thrombosis occurring in mentally ill patients are presented, with a brief review of the problem of diagnosis.

MALE STERILITY

WALTER W WILLIAMS, M.D.†

SRINGFIELD, MASSACHUSETTS

THE significance of male sterility is best realized if one considers that about one out of seven marriages are barren, and that in about half these matings the husband is either directly or indirectly responsible for the reproductive failure. The problem of male sterility therefore occupies so important a place in sterility investigations that a lack of adequate consideration must inevitably lead to a greatly reduced validity of diagnosis and consequently to much misdirected or useless treatment of both the female and the male partner.

A vast number of normal appearing and acting spermatozoa are usually required to supply a single cell capable of impregnating an ovum. All male sterility is essentially the result of a diminished availability of normal spermatozoa during the fertile phase of the menstrual cycle. For purposes of discussion, male sterility can conveniently be classified under five headings, according to the degree of availability of normal spermia: faulty delivery of spermatozoa; germ plasma aplasia; germ plasma hypoplasia; germ plasma dysplasia, and asthenospermia.

Faults in Delivery

The recognition of faults in the delivery of spermatozoa constitutes no great problem either in

diagnosis or in the incidence of occurrence. A simple examination of the semen to find out if spermatozoa are present in the seminal fluid and a history that takes into consideration the character of the coital act, together with a physical examination of each partner, should be quite adequate in all cases to clear up this point.

Germ Plasma Aplasia

In germinal aplasia, there is a degeneration or lack of development of the germinal epithelium, so that the patient is entirely incapable of spermatogenesis. Accordingly, no spermatozoa are delivered in the seminal fluid. Testicular biopsy furnishes the only reliable means by which germinal aplasia may be differentiated from the azoospermia of epididymal obstruction, and should be employed in all cases of azoospermia before any type of therapy is attempted. A history and physical examination often provide very inconclusive diagnostic information, since with hypoplasia the testes may not be diminished in size or altered in texture, and in epididymal obstruction a perceptible enlargement or thickening of the epididymis may not be apparent. A history of gonorrheal infection is highly suggestive that the trouble is due to epididymal disease, but furnishes far from conclusive evidence.

FIGURE 1. Normal (upper) and Abnormal (lower) Sperm Populations.

Although there is considerable variability among normal spermatozoa, the size and contour are fairly regular, in contrast with those of abnormal spermatozoa.

a = acrosome; b = nucleus; c = neck; d = body; e = posterior end knob; f = anterior end knob; g = tail; h = cytoplasmic extrusion; i = abnormal nucleus; k = microspERM, with deficient acrosome; n = normal sperm head.

Germ-Plasm Hypoplasia

Germ-plasm hypoplasia signifies an inability of the germinal epithelium to maintain a normal rate of spermatogenesis. The diagnosis is made with the aid of a blood-counting chamber, and the count should be made on a specimen obtained after a period of four or five days' sexual rest. Frequency of intercourse, even in normal persons, may reduce temporarily the number of spermatozoa in a given ejaculate, and accordingly it is well that a low density count should always be rechecked with another sample obtained under known conditions. A moderate hypoplasia with a normal sperm population may be of little clinical significance, and warrants a relatively good prognosis, particularly if the case is handled properly from the medical point of view and a sexual overload is avoided.

Germ-Plasm Dysplasia

Male germinal dysplasia offers quite a different problem than a simple germinal hypoplasia, for there is a fundamental defect in the germ plasm so that a part of or all the germinal epithelium becomes incapable of reproducing other than defective spermatozoa. At times, an alteration occurs in the ratio of normal and abnormal spermatozoa in different samples from the same person, a finding that is apparently due rather to differences in the rate of spermatogenesis in the healthy and abnormal elements of the germinal epithelium than to any fundamental improvement in the germ plasm as a whole. The diagnosis of germ-plasm dysplasia depends on the examination of properly stained smears of semen and the determination of the type and ratio of spermatogenic abnormalities. Even the use of testicular biopsies is inadequate for the diagnosis of a dysplasia, since the spermatozoa seen in a biopsy are cut in different planes, rendering the recognition of abnormalities of the mature spermatozoa literally impossible. As a result of the rather widespread failure to study adequately stained specimens of semen, the whole matter of germinal hypoplasia, dysplasia and asthenospermia has been badly jumbled.

Dysplastic germinal epithelium is frequently less capable of producing normal numbers of spermatozoa than normal germ plasm, and the association of hypoplasia and dysplasia is accordingly a common feature; although it carries with it an extremely unfavorable prognosis, one should remember that fertilization is always possible if any apparently normal spermatozoa are found in the ejaculate. If all spermatozoa are abnormal, even if they occur in normal numbers and are highly active, one need have no hesitancy in rendering a hopeless prognosis. When the growth potentialities of the germ plasm have been completely altered, there

is no more likelihood of benefit from any form of therapy than one would obtain by altering the growth potentialities of other tissues of the body.

In most cases of sterility, only a portion of the germ plasm is dysplastic, and accordingly millions of normal appearing and acting spermatozoa are usually mixed in the ejaculate along with imperfect spermatozoa. Clinical experience with human and animal semen examinations suggests that the agent or agents responsible for the visible effects on a portion of the germinal epithelium also act on the more normal appearing elements to reduce their fertilizing ability according to the extent of damage. This damage and the fertilizing potentialities of a sperm population are best estimated on the basis of the extent of observed abnormalities, together with a consideration of the rate of spermatogenesis. In most cases of sterility resulting from germinal dysplasia, there exists a wide variety of bizarre abnormal forms, which have resulted from variations affecting either the nucleus or the acrosome. Since, in structurally abnormal spermatozoa, the nucleus and acrosome are usually involved, it follows that if a sperm population is broken down into four groups (Fig. 1), one containing normal appearing spermatozoa, another presenting nuclear abnormalities, a third with acrosomic defects and a fourth containing the miscellaneous assortment of other abnormalities, one will obtain a fairly reliable idea of the constitution of the sperm population and, thereby, a basis for estimating fertilization potentialities. The latter is far from an exact science, but is nevertheless an indispensable part of any sterility diagnosis that aims at reliability.

Asthenospermia

In other cases, there is evidence that the ability to fertilize the ovum is diminished, in spite of the normal appearance of the sperm population. The motility of such populations may or may not be impaired, and the semen examination alone provides an extremely poor means for arriving at a valid diagnosis. This condition, commonly known as asthenospermia, results from a variety of etiologic factors. Patients with a low basal metabolic rate and those presenting a chronic prostatitis furnish good examples, for, as in other somatic conditions, there is often clinical evidence of impaired fertility without structural alterations in the spermia or faulty spermatogenesis. One must thus recognize the existence of cases in which functional defects without a demonstrable lesion lower the fertilizing ability of the sperm population, but the diagnosis is hardly justified unless a careful examination fails to reveal the presence of significant spermatogenic abnormalities, and unless the anamnesis and the somatic examination together with

general laboratory studies show the presence of some factor that might reasonably impair the vitality of the spermatozoa.

Relation of Male and Female Sterility Studies

The diagnosis, prognosis and treatment of male and female sterility are so interdependent in vari-

expected ovulation (Fig. 2). No arbitrary means of calculating the ovulation date will suffice in sterility work because of the marked variation of ovulation time and the extreme brevity of the period during which fertilization is possible. As a result, when there is an indication for a severe restriction of sexual relations, there must be a

FIGURE 2. Case 229.

This chart records the basal body temperatures and vaginal smears during two menstrual cycles (actual menstruation indicated by arrows) in a twenty-six-year-old woman who had been married for seven and a half years. No contraceptives had been used, but conception had never occurred. The woman was normal. The husband, who was thirty years old, presented severe germinal hypoplasia (3700 spermatozoa per cubic millimeter) and severe germinal dysplasia (56 per cent pathologic spermatozoa). Conception occurred at the first timed intercourse after four weeks of sexual inactivity.

X = sexual relations; PoM = postmenstrual type of vaginal smear; Ov = ovulatory type of vaginal smear.

ous aspects that little constructive work on the husband is to be expected from studies not closely related to studies on the wife. For example, in germinal hypoplasia and dysplasia, a restriction of relations to the fertile phase of the menstrual cycle is often highly desirable, and accordingly it becomes necessary to subject the wife to routine objective tests and to estimate each month the date of

careful timing to the fertile phase, or the chance of fertilization may be missed altogether.

SUMMARY

The various causes of male sterility are discussed, and the need for closely correlated studies of husband and wife is emphasized.

MEDICAL PROGRESS

WOUND HEALING*

ARTHUR D. HOLMES, PH D †

BOSTON

WOUND healing has occupied the attention of man through the entire human era, for without doubt the prehistoric man received wounds and tried to cure them. In fact even animals adopt procedures for treating wounds. The muskrat caught in a steel trap amputates his foot and applies his own treatment for healing the wound. And, who has not seen a dog lick his wound in an attempt to allay pain and promote healing?

During human existence literally thousands of substances have been suggested for promoting wound healing, but obviously it is impossible within the scope of this paper to cover all the materials that have been recorded in the literature for stimulating the growth of new tissue in wounds. Accordingly attention will be confined to a number of factors and materials that have been the subject of investigations reported during recent years. These are the influence on wound healing of diet, hydrogen ion concentration, zinc peroxide, maggots and urea, sulfhydryl compounds, sulfonamides, gramicidin and penicillin, tissues and tissue juices, vitamins and cod liver oil. An attempt will be made to discuss these topics as separate entities, but it will be seen that there is frequent overlapping. For instance, it is extremely difficult, if not impossible, to eliminate completely the influence of the diet on wound healing when attempting to evaluate the therapeutic activity or value of substances such as sulfonamides or cod liver oil, for promoting the growth of tissues. In a measure the factors and substances discussed may be divided into two classes: those used for inhibiting the growth of or killing organisms found in wounds, and those used for stimulating tissue growth. But this classification cannot be followed completely since some of the factors and materials do not belong entirely in either group.

DIET

Wound healing obviously requires the growth of new tissues, which involves the production of

protein characteristic of the subject. Carbohydrates and fats are also essential for satisfactory metabolism in the wounded as well as in the normal individual. Thus the question of the influence of the diet on wound healing has been a subject of much interest to investigators.

Harvey and Howes,¹ in studying the effect of high protein diet on the velocity of growth of fibroblasts in the healing wound, found that during the latent period it had no effect, but once growth was started the velocity of healing was distinctly increased by a high protein regime. As a consequence the maximum strength of the healing wound was reached two days earlier than with a standard diet. Thompson, Ravdin and Frank,² in experiments with dogs, demonstrated a relation between hypoproteinemia and the disruption of surgical wounds and showed that the hypoproteinemic dog is frequently incapable of wound fibroplasia. Burrows³ states that the connective cells except where they are very closely packed together in a wound cannot destroy the fibrin, but they do take fats, serum proteins and evidently other substances from the blood clots.

Rhoads, Fliegelman and Panzer⁴ promoted wound healing in hypoproteinemic dogs by injecting large amounts of acacia, which they assume tends to mobilize protein for utilization but they caution that this treatment is not justifiable for treating human wounds. Clark⁵ has assembled data concerning the effect of the principal ingredients of the diet on wound healing. Four groups of three dogs of the same size, age and condition were fed a mixed, a carbohydrate, a protein and a fat diet for three days, after which they were anesthetized and wounds were made in their backs. The experimental diets materially influenced the length of the quiescent period of wound healing. There was no quiescent period for the protein fed dogs, the period was three days for the carbohydrate fed dogs, four days for the dogs that received the mixed diet, and six days for the fat fed dogs. The effect of the diet on the length of the quiescent period was greater for small than for large wounds, but in all cases the scar was one quarter the size of the original wound.

*Reprints of articles in this series are not available for distribution but the articles will be published in book form. The current volume is *Medical Progress Annals Vol III 1947* (Springfield Ill no 3: Clark et al. The new lancet 7 1946 \$5.00).

†From the Research Laboratories E. L. Patch Company Boston. Formerly director of research E. L. Patch Company now research professor of chemistry Massachusetts State College Amherst.

A number of investigators have commented on the importance of the diet during the treatment of various lesions. Whipple⁶ states that a protein deficiency retards but a high-protein diet accelerates wound healing. He also noted that a high-fat diet prolongs the period of repair in wounds. Weil, Whitaker and Rusbridge⁷ state that a high-protein, high-vitamin diet should be used in the treatment of wound cases. Holman⁸ has carefully observed the influence of the diet in preoperative and postoperative care of the surgical patient, and recommends a high-calorie, high-vitamin diet for two weeks preceding an elective operation. Strumia, Wagner and Haylar,⁹ in discussing the management of shock and treatment of burns, emphasizes that a high-calorie high-polyvitamin diet is indicated for promoting the growth of tissue in burned areas.

It is generally agreed that for continued health and bodily well-being the human dietary should supply adequate amounts of several vitamins, but only three, vitamins A, D and C, will be considered at this time. For convenience vitamins A and D will be considered together.

Vitamins A and D

Roegholt¹⁰ did not find that vitamin A deficiency affected the rate of healing in epithelial wounds. Saitta¹⁰ reported that the rate of healing of epithelial wounds on animals that had received a vitamin-A-deficient diet for sixty-six days did not differ from that of controls. When the vitamin-A-deficient diet was continued for one hundred and five days the wounds remained unhealed, became infected, and the animals died, but when wounds were painted with a vitamin A extract they healed in thirteen days. Lauber¹⁰ found that pretreatment of rats with vitamin A did not affect the rate of healing in wounds subsequently produced. However, oral administration of the vitamin following the infliction of skin wounds produced remarkable acceleration in healing. Some lesions healed in nine days, as compared with eighteen to twenty-five for controls. When 200 units per day was administered there was no noticeable effect on the rate of healing. When 40,000 units was administered, however, healing required thirty-six to fifty-two days. Bailey¹¹ believes that vitamin A deficiency decreases the effectiveness of the epithelial barrier to infection. Tammann¹⁰ found that overdosage with vitamin D delayed wound healing. Lauber¹⁰ failed to produce any effect on the healing time in rats by foretreatment or concurrent treatment with varying doses of vitamin D, including overdosage, but thinks that these results do not afford safe conclusions for application to human therapy.

Vitamin C

Wolbach and Howe¹² characterize scorbatus as the inability of supporting tissues to produce and maintain intercellular substances, and believe that such failure is due to an inadequate supply of ascorbic acid. Smith and McConkey¹³ found that scorbutic guinea pigs were liable to develop duodenal ulcers. Experimental wounds in such animals healed completely with no abnormalities when the animals received canned tomato juice daily, but no healing occurred in wounds of similar animals receiving no vitamin C supplement, and coincidentally 80 per cent of the animals developed ulcers of the duodenum.

Whipple⁶ concludes that vitamin C deficiency prolongs the healing process, and he suggests that even if peptic ulcer patients have no vitamin C deficiency when admitted to the hospital, only four days of strict ulcer dietary regime will cause them to develop this deficiency. Davidson¹⁴ found that patients receiving an ulcer-producing (vitamin-C-deficient) diet developed deficiency disease, and emphasizes the necessity of including adequate accessory food factors in special diets to prevent development of deficiency diseases. Ingalls and Warren¹⁵ determined the vitamin C contents of the blood plasma of 20 patients with gastric or duodenal ulcers, 18 (90 per cent) of whom had low vitamin C values. They emphasize the importance of the clinician's being sure that his patients receive an amount of vitamin C adequate to promote wound healing. Holman⁸ found that a vitamin-C-deficient diet retarded the healing in 44 per cent of 70 patients and that ascorbic acid is essential for the synthesis and maintenance of intercellular supporting materials. He recommends that in elective operations, such as hernia, the patients receive generous amounts of ascorbic acid for two weeks preoperatively to ensure rapid healing of wounds. Lanman and Ingalls¹⁶ present evidence that even a partial vitamin C deficiency has important bearing in the treatment of surgical wounds and that administration of ascorbic acid to promote wound healing is indicated.

Hunt¹⁷ states that, as early as 1772, James Lind noticed a relation between scurvy (vitamin C deficiency) and delayed wound healing. He points out that vitamin C deficiency is particularly prevalent in patients with gastrointestinal diseases and that most wounds break down on about the tenth day, but that this condition may be eliminated by saturating patients with vitamin C. One thousand milligrams daily for three days produces saturation, and 100 mg. daily thereafter maintains it.

Lund and Crandon¹⁸ report that vitamin C reserves in the tissues or in the tissue cells, not the blood-plasma level, are the determining factor in healing. They examined 58 patients one year after operation and found that those with low preoperative blood plasma levels had a larger percentage of postoperative hernias after gall-bladder operations than did those with high levels. They recommend that patients with low reserves receive preoperative and early postoperative treatment with vitamin C.

Archer and Graham¹⁹ observe that following long periods of ill health or strict diet patients are likely to be in a subscurvy state. Thus many patients on a strict diet due to gastric or duodenal ulcers lack ascorbic acid in their body. Hence, for ulcer patients these authors recommend 1000 mg. of ascorbic acid for three successive days to saturate the body, and then a daily dose of 36 mg.

Platt²⁰ reports 4 cases of adult scurvy seen in private practice. One patient was a neurotic woman who had dieted; 3 were peptic ulcer patients on dietetic treatment. Administration of vitamin C from natural or artificial sources cured the scurvy that had resulted from the prolonged treatment with diets lacking vitamin C.

Hartzell, Winfield and Irvin²¹ report that a group of patients with clean wounds and apparently uneventful convalescence experienced disruption of wounds without warning and without apparent physical cause. The levels of plasma vitamin C and serum protein were low. The relation of these factors to poor wound healing cannot be overlooked. In discussing vitamin therapy in practice Vorhaus²² stresses the importance of vitamin C both before and after operation. Madison and Manwaring²³ have shown experimentally that vitamin C aids the body in defense against infectious diseases and a large dose increases antibody production.

Crandon, Lund and Dill²⁴ concluded from a study of human scurvy that total vitamin C deficiency causes failure of wound healing. Microscopically the tissues showed a lack of intercellular substance, but parenteral administration of vitamin C produced good healing and considerable intercellular substance within ten days.

In discussing the prevention of infection in wounds and burns, the Committee on Chemotherapeutic and Other Agents and the Committee on Surgery of the Division of Medical Sciences of the National Research Council²⁵ state that a reduction of vitamin stores, especially vitamin C, interferes with normal wound healing, and they recommend the daily oral administration of 75 mg of ascorbic acid until recovery is complete.

The significance of vitamins applied locally will be considered later, but the data cited above indicate the importance of a carefully selected dietary in the treatment of accidental or surgical wounds, particularly if they are extensive.

HYDROGEN-ION CONCENTRATION

Practically everyone has at some time experienced definite discomfort when sweat, salt, soap, acid or some other substance has entered his wound. However, very few have associated this unpleasant experience with a change in the hydrogen ion concentration of the wound, but a number of investigators have determined the hydrogen-ion concentration of wounds subjected to different types of treatments.

Messer and McClellan²⁶ measured the pH of healing wounds by placing contact electrodes in them. In all cases the fluctuations in pH followed roughly the clinical conditions of the wounds; progressive healthy healing was accompanied by consistent increase in alkalinity, whereas failure of healing was followed by fluctuations toward acidity. Wounds that healed rapidly with pinkish granulation tissue and flat, undistorted scar tissue showed an alkalinity of pH 7.4. Messer and McClellan believe that excess alkalinity is a factor in bacteriostasis and wound healing.

Hashizume²⁷ is not in agreement with this conclusion. He determined the pH of the secretions of infectious and noninfectious wounds of man under various conditions and found that regardless of favorable or unfavorable conditions for wound healing, the pH quickly approached that of the tissue or blood if the wound surface was exposed to the air. He concludes that change in pH does not parallel the course of healing but is correlated with the rate of escape of carbon dioxide. In his extensive studies of the value of chloramine-T for promoting wound healing, Carrel²⁸ observed that it was nonirritating to the tissues. Chloramine-T U.S.P. (1:20)²⁹ must be alkaline and thus has a pH in excess of 7.0.

Reimers and Winkler³⁰ produced acidosis in dogs by the administration of ammonium chloride, and found a definite shortening of the period of wound healing.

Robinson³¹ states that 2 per cent solutions of ammonium bicarbonate (pH 7.7) promote healing of such conditions as chronic osteomyelitis, stich abscesses, chronic varicose ulcers and lacerations, with the formation of little scar tissue and in some cases return of the hair to the surface of the wound.

Rohde³² reports that chronically inflamed granulation tissues tend to have an acid reaction, with pH values ranging from 6.8 to 7.1. Arcy³³ found that pain in aseptic wounds was related to the local

acidity. Injections of buffered acid phosphate solution are painful but those of buffered alkaline phosphate solution produce no pain. He suggests that the strong pain of inflamed wounds is related to local acidity; thus pain in abscesses, ulcers and allied conditions can be relieved by the injection of buffered alkaline phosphate solution. Human experiments showed that pain began at pH 7.2 and increased progressively until at pH 5.9 it was unbearable.

The results of these studies are practically unanimous in indicating that a pH in excess of 7.0 is desirable for enhancing the patient's comfort and providing a condition favorable for rapid tissue growth.

ZINC PEROXIDE

For many years it has been recognized that rapid oxidation greatly inhibits the activity of pyogenic bacteria found in wounds. Hydrogen peroxide has been very extensively used, but during recent years considerable attention has been given to the value of zinc peroxide as an oxidizing agent for treating wounds.

Bliss, Long and Smith³¹ applied zinc peroxide locally and found it highly active in controlling infection due to *Clostridium oedematiens*; when used intramuscularly in the treatment of *Cl. tetani* infections in mice, it was much more effective than sulfathiazole. They found wide variation in the effect of zinc peroxide in different types of infections. It produced excellent results in the therapy and prophylaxis of *Cl. tetani* and *Cl. oedematiens* infections but was far below sulfadiazine in controlling *Cl. septique* and was practically worthless against *Cl. welchii*. On the other hand, Johnson and Meleney,³² who tested sterilized medicinal-grade zinc peroxide on a variety of organisms, report that *Cl. welchii* and *Cl. tetani* were the most susceptible to its action; hemolytic streptococcus, pneumococci, *Cl. histolyticum*, *Cl. sporogenes*, *Cl. novyi* and *Cl. sordellii* were less sensitive; and *Streptococcus viridans*, *Staphylococcus aureus*, *Escherichia coli*, *Proteus vulgaris* and *Pseudomonas pyocyaneus* were relatively resistant.

Friel³⁶ studied the value of ionized zinc in the treatment of suppurating surfaces. Layers of gauze soaked in sterilized solution of zinc sulfate in gelatin were laid on the raw area, a positive electrode was kept in contact by a bandage, and at intervals cultures were made from the surface. The advantage of the zinc ionization is the speed with which suppuration may disappear. Friel believes that suppuration ceases because zinc albuminate is a bad culture medium for micro-organisms and causes no irritation to the wound. Gurewitsch³⁷ treated 15 patients with indolent ulcer by placing

zinc peroxide paste on the ulcer, covering it with a gauze pad saturated with saline and applying a positive electrode.

Meleney³⁸ recommends zinc peroxide for prevention of the growth of organisms in grossly contaminated wounds, particularly around the mouth, colostomies, anus, fistulas and pilonidal cysts where anaerobic organisms are known to be involved. He recommends its use as a prophylactic against infection of the peritoneal cavity after appendectomy or abdominal resections of the bowel, and states that if streptococci or *Cl. welchii* is present in a closed wound it should be opened and zinc peroxide applied. He further states that zinc peroxide acts best if it is kept wet, and that, although tissue fluids will activate it, distilled water or 2 per cent polyvinyl alcohol will keep it wet longer.

An editorial states that zinc peroxide has been used successfully in the dangerous human bite, perirectal and deep pelvic abscesses, and gas-gangrene, and that combined with glyceryl monostearate and peanut oil as a base it is a powerful therapeutic weapon against all anaerobic bacteria and hemolytic streptococci.³⁹

Noel and Lynn⁴⁰ report the variability of results obtained from zinc peroxide therapy. They conclude that no true substance of this composition exists, and that the commercial products are probably chemical or physical combinations of zinc oxide with hydrogen peroxide, their value being proportional to the amount of available oxygen, established by assay. The rapid drying of pharmaceutical preparations, previously a serious handicap in practice, has been largely overcome by the incorporation of sorbitol, but mannitol does not produce such satisfactory results.

Although numerous investigators have found freshly prepared zinc peroxide effective for killing pyogenic bacteria in wounds, it leaves a zinc oxide residue; also it would doubtless deteriorate in preparations stored for considerable periods.

MAGGOTS — ALLANTOIN AND UREA

It was frequently observed during World War I that wounds that had become infested with maggots healed more satisfactorily than those that had received more prompt attention. However, this was not an original observation, for some three centuries ago Ambroise Paré⁴¹ was aware of the beneficial results of live maggots in wounds. Also a century or more ago Larrey⁴¹ noted that the wounds of Syrian soldiers were benefited by the presence of maggots, and that the latter consumed only dead and decomposed tissue and did not touch live tissues. Keen⁴¹ says that during the Civil War wounds were frequently infested with maggots, but they never caused harm and

were frequently beneficial Baer⁴² found that maggots removed fragments of bone and tissue sloughs,—an asset in wound healing,—caused wounds to become alkaline, thus inhibiting the growth of pathogenic bacteria, and contributed some subtle biochemical effect within the wound. He also found that maggot treatment of open tuberculous abscesses, with or without infection, was surprisingly effective. Messer and McClellan,⁴³ in studying the functions of surgical maggots in wound healing, observed that osteomyelitis wounds treated with blow fly larvae showed rapid cleansing, pinkish granulation tissue and a flat, undistorted scar.

Robinson⁴³ noted that the excretion of maggots contained allantoin, and when it was used for treating experimental wounds, results similar to those produced by maggots were obtained. However, nearly a quarter of a century earlier Macalister⁴⁴ had treated chronic ulcers with a solution of allantoin and obtained healing with rapid granulations. He also successfully used allantoin internally for treating gastric and duodenal ulcers. In later investigations Robinson⁴⁵ found that the maggot excretion also contained urea, and when this was tested on human wounds it was found to possess definite healing value.

Holder and MacKay⁴⁶ treated 139 cases with urea without any deleterious effects and obtained their best results with chronic ulcers. They found that urea was nontoxic and harmless, a solvent of dead tissue, dried secretions and other materials that hinder healing, and bacteriostatic in strong solutions. In a later paper they⁴⁷ noted that hypertonic solutions of urea may be painful to denuded tissues, and suggest that iso amyl hydrocupreine be combined with the urea for its local anesthetic action. Millar⁴⁸ states that urea is cheap and readily available, does not irritate tissue, has some antiseptic value, causes no systemic reactions, and is very effective in eliminating odors, particularly the peculiar penetrating fetor of sloughing cancer. Robinson⁴⁹ found that urea stimulates the growth of granulation tissue and the development of capillaries, is easily prepared for use by adding to cold, sterile distilled water, and is effective in the treatment of such purulent conditions as varicose and diabetic ulcers, carbuncles, suppurating x-ray burns, infected heat burns, intraoral infections, osteomyelitis and skin infections. Foulger and Foshay⁴⁹ used urea successfully in 20 cases of purulent otitis media that had failed to respond to other medicaments. The discharge lost the foul odor, became serous, and in three to six days ceased, even though it originally contained hemolytic streptococci. Unfortunately the urea caused pain, which was controlled with morphine. Wilson⁵⁰ states that an

8 per cent solution of urea prevents the growth of *Esch coli*. Symmers and Kirk⁵¹ successfully treated chronic staphylococcus infection with urea. Wilson reports that small amounts of urea added to nutrient mediums have a distinct effect on *Esch coli*, *Eberthella typhosa*, *Salmonella enteritidis*, *Ps pyocyanea* and Friedlander's bacillus. Olson, Shider, Clark and MacDonald⁵² found that urea retards the rate of epithelization of open skin wounds of rabbits but stimulates the rate and extent of granulation tissue.

The investigators cited above are apparently in complete agreement that urea is a valuable material for promoting wound healing, particularly for removing debris and necrotic tissues. However, to be effective, concentrated solutions (30 per cent or more) must be used, and in some cases these cause the patient discomfort and sometimes require sedation.

SULFHYDRYL COMPOUNDS

In considering the effect of sulfhydryl compounds on wound repair, Riley⁵³ is of the opinion that they stimulate growth by mitosis. Reimann and Hammett⁵⁴ report treating aged persons with varicose, decubitus and trophic ulcers with thioglyucose solution, 1:10,000, as a wet dressing and thus stimulating granulations and epithelial growth. However, this product also promotes bacterial growth, which in turn inhibits healing. Consequently sulfhydryl solutions should not be used for more than twenty-four hours, with intervals of two or three days between treatments. Pierce⁵⁵ thinks that sulfhydryl compounds are of great importance in tissue growth and are best applied to burns as compresses. Most patients complain of pain when a sulfhydryl solution is applied to the burned area but this does not persist over one or two hours. Reimann⁵⁶ reports using a sulfhydryl preparation on decubitus and pressure ulcers, one of which had not healed after six months' treatment with other preparations. Para-thiocresol, 1:10,000, produced healthy granulations within forty-eight hours. However, treatment was stopped for three days, during which time physiologic sodium chloride solution was applied, after which the *p*-thiocresol treatment was repeated. Sulfhydryl solutions must always be made fresh, and they have a disagreeable odor. Fitzhugh⁵⁷ in studying the effect of sulfhydryl compounds in otolaryngology found that they could not be used in the presence of marked, purulent exudate. After granulation has started *p*-thiocresol can be applied and will promote epithelial growth. When applied to postauricular incisions, healing occurs in three or four days.

A number of investigators have shown that sulfhydryl compounds possess unusual value for stimulating tissue growth. Unfortunately they

also stimulate the growth of organisms present in wounds, and consequently in the treatment of lesions they should be used alternately with other types of medication.

SULFONAMIDES

Although sulfanilamide was synthesized thirty years or more ago, it is only within the last six or eight years that attention has been given to the remarkable bactericidal power of the sulfonamides. Even so, the present volume of literature concerning them is so extensive that only a limited number of investigations can be included.

According to Buttle,⁵⁸ the value of sulfonamides in the treatment of human wounds is due to their ability to inhibit bacterial growth with little or no harmful effect on the phagocytic cells. Huang and Sia,⁵⁹ Fuller and James,⁶⁰ Colebrook and Francis,⁶¹ Buttle⁵⁸ and others report that sulfanilamide applied to a wound inhibits growth of the hemolytic streptococcus and of the gas-gangrene organisms, particularly *Cl. welchii*.

Most of the deaths from infection⁶² in World War I were due to hemolytic streptococci and gas-gangrene organisms. Sulfanilamide is particularly effective against these bacteria. Fuller and James⁶⁰ recommend that the first dose of 1.5 gm. be placed in the wound as soon as possible. Delay is dangerous. If several hours have elapsed, the amount administered orally in the first doses should be increased. Beginning two hours after the first dose intact 0.5-gm. tablets should be given at four-hour intervals. Prophylaxis must be continued for at least four days to counteract hemolytic streptococcus infections which may occur in the hospital. Coated tablets used to secure prolonged retention of the drug do not offer any advantages. Colebrook and Francis⁶¹ studied the effect of sulfanilamide powder on sixty-two superficial wounds infected with hemolytic streptococci. The organism disappeared from the wounds within three or four days, but infections with Group D streptococci, staphylococci, *Prot. vulgaris* or *Ps. pyocyanea* were resistant to local sulfanilamide treatment. Jackson and Collier⁶³ recommend the local use of sulfanilamide in peritonitis and conclude that it causes no injury to the peritoneal surfaces. Jensen, Johnsrud and Nelson⁶⁴ treated forty-one wounds associated with compound fractures with 5 to 15 gm. of sulfanilamide. The wounds healed by first intention in all but 2 cases, but before the use of sulfanilamide the infection rate was 27 per cent. Blood assays showed that after local treatment the maximum concentration of sulfanilamide in the blood occurred in eighteen hours. Purdie and Fry⁶⁵ administered a total of 94 gm. of sulfanilamide to a patient with several discharging wounds

containing hemolytic streptococci and *Esch. coli* that had remained unhealed for three years, in spite of operative procedures and actinotherapy. Four days later the wounds discharged less, in twenty-three days they were nearly healed, and after forty-four days they were completely healed. In discussing compound fractures complicated with gas-gangrene, Bohlman⁶⁶ states that sulfanilamide has a specific effect on gas bacilli, but cautions that conservative surgical principles must be combined with its use. Gibbon and Hodge⁶⁷ are of the opinion that sulfanilamide should be employed locally and orally in all patients with traumatic wounds.

In comparing the absorption of the various sulfonamides, Hawking⁶⁸ found that 0.2 gm. of sulfanilamide inserted in an experimental wound in a guinea pig's thigh was absorbed in less than twenty-four hours; sulfathiazole in four or five days, and sulfapyridine in seven to ten days. Sulfanilamide placed in one end of an 8-cm. wound produced high concentration at the distal end in two hours, sulfathiazole and sulfanilylguanidine high concentration in two to six hours, sulfadiazine moderate concentration in six to twenty-four hours, and sulfapyridine low concentration in twenty-four hours.

From their experience in the Libyan campaign, Mitchell, Logie and Handley⁶⁹ emphasize both oral and local administration of sulfonamides, since their patients so treated were fitter and showed less local sepsis than did controls. They suggest applying 15 gm. of sulfanilamide immediately to the wound and 15 gm. more after operation. Twenty-seven grams is administered orally to the patient in six days.

Numerous investigators have recommended the local application of sulfonamides to various types of wounds. Miles⁷⁰ says that even in the presence of pus they reduce streptococci, staphylococci, coliform bacilli and sporebearing anaerobes when applied locally to wounds, and recommends both local and oral administration of sulfathiazole. Griswold and Antonie⁷¹ recommend the local implantation of sulfanilamide in the abdomen for perforated peptic ulcers, perforated appendicitis or gunshot wounds, or when the lumen of the gastrointestinal tract is opened; and the Committee on Chemotherapeutic and Other Agents and the Committee on Surgery of the Division of Medical Sciences of the National Research Council⁷² recommend the liberal application of crystalline sulfanilamide to all wounds as soon as possible after they are incurred.

Although it is generally recognized that sulfonamides are used in the treatment of wounds for their bactericidal activity, a number of investiga-

tors have referred to their influence on cell growth. Livingston,⁷² Mayo and Miller,⁷³ Guerry and Putney⁷⁴ and Thompson, Brabson and Walker⁷⁵ think that sulfanilamide and sulfathiazole stimulate tissue growth. Kev, Frankel and Burford.⁷⁶ Kev⁷⁷ and Key and Burford⁷⁸ believe that sulfanilamide does not seriously interfere with wound healing. Goldberger⁷⁹ states that wound healing is not appreciably inhibited by the sulfonamides. On the other hand, Bick⁸⁰ reports that the local application of sulfonamides to wounds retards healing by 50 per cent and promotes excessive cutaneous scarring. Lyons and Burbank⁸¹ believe that local applications of sulfanilamide delay wound healing.

Fleming,⁸² Kolmer and Brown,⁸³ Lockwood⁸⁴ and others have found that such materials as thick suspensions of bacteria, peptones, dead streptococci and tissue residues inhibit the bacteriostatic action of sulfanilamide. Rubbo and Gillespie⁸⁵ found that as little as 1 part of *p*-aminobenzoic acid reverses the bacteriostasis of 26,000 parts of sulfanilamide, and Weil, Whitaker and Rusbridge⁷ report that novocain is an inhibitor and is contraindicated for cases in which sulfathiazole is to be used.

Jones⁸⁶ recommends that a cod-liver oil emulsion containing 5 per cent sulfanilamide be used routinely for wounds, but Locatelli and Bowden,⁸⁷ Fitch⁸⁸ and Pillsbury, Wammock, Livingood and Nichols⁸⁹ say that an emulsion with an oily base retards and reduces the activity of sulfanilamide.

Mueller⁹⁰ believes that sulfanilamide must be sterilized before being placed in the abdominal cavity. Thompson, Brabson and Walker⁷⁵ are of the same opinion and recommend heating the drug in test tubes at 120°C. for half an hour. On the other hand, Key and Lembeck⁹¹ think this unnecessary, since pathogenic organisms will not be carried into the wound in the sulfanilamide powder, and Herrell and Brown⁹² hold that there is no necessity for sterilizing sulfanilamide or sulfathiazole powder before direct application to an open wound.

Very recently a number of investigators have described undesirable side reactions of varied nature and intensity which have been noted following the administration of the sulfonamides. In the case of sulfanilamide, Weitzen⁹³ has observed angular and curvilinear distortions, disturbed distance perception and micropsia in his patients; Higgins⁹⁴ reported aphasia and stammering on the third day of sulfanilamide medication; Pearson and Burnstine⁹⁵ have called attention to a series of cases of psychoses; Garvin⁹⁶ described a patient who became irrational and confused after a single dose of sulfanilamide; Ottenberg⁹⁷ reported death following toxic psychosis; Waugh⁹⁸ observed 1 case of peripheral neuritis among 650 patients;

Janet⁹⁹ commented on a case that developed neuritis of the arm and thorax; Ornstein and Furst¹⁰⁰ described a case of dystrophic gait and patchy distal hypesthesia; Fisher and Gilmour¹⁰¹ noted encephalomyelitis; Bucv¹⁰² observed toxic optic neuritis after a single 0.3-gm. tablet of sulfanilamide and Blankstein¹⁰³ reported transitory myopia.

Similar reports appear in the literature relative to the undesirable effects that develop after the administration of sulfathiazole. For instance, Weinberg and Knoll¹⁰⁴ noted a syndrome resembling amyotrophic lateral sclerosis; Stiles¹⁰⁵ called attention to hypersensitivity to even small doses of the drug; Finland, Peterson and Strauss¹⁰⁶ emphasized that such complications as drug fever, rash and granulocytopenia may follow its ingestion; Penner and Horack¹⁰⁷ reported transient renal complications following its administration; Loewenberg, Sloane and Chodoff¹⁰⁸ found at autopsy concretions in the kidneys, ureters and bladder of a case so treated; Cutts, Burgess and Chafec¹⁰⁹ reported a 10 per cent death rate and nitrogen retention in a series of patients who received the drug; Hoyne and Larimore¹¹⁰ observed gangrenous pharyngitis and laryngitis, focal membranous tracheitis, focal hemorrhagic bronchopneumonia and swelling of the myocardium, liver and kidneys at autopsy following death attributable to the ingestion of sulfathiazole; and Lederer and Rosenblatt¹¹¹ commented on the pathology in 4 cases in which death was attributable to this substance. Evidence published by Lyons and Balberor¹¹² indicates that approximately one third of all patients develop a sensitivity to sulfonamides sufficient to interfere with their subsequent use. Gallagher¹¹³ says that this type of sensitivity may persist for at least two years. Little¹¹⁴ reports the following abnormal conditions due to the use of sulfonamides: aphasia, stammering, toxic psychosis, peripheral neuritis, myelitis, optic neuritis, transitory myopia, meningeal signs, blindness and convulsions.

It is quite evident from this brief review of the literature of the sulfonamides that they have powerful bactericidal effect and are of great value to the surgeon and for wound treatment, but it is also evident that they possess undesirable qualities and can cause great damage unless administered under carefully supervised conditions.

GRAMICIDIN AND PENICILLIN

A number of years ago Dubos¹¹⁵ observed an unidentified sporebearing bacillus isolated from a sample of soil that rapidly killed pneumococci, streptococci and staphylococci when incubated with them at 37°C. but did not affect the virility or inhibit the growth of gram-negative bacilli. Dubos and Cattaneo¹¹⁶ prepared cell-free extract by re-

moving the protein precipitable at pH 4.5. The purified preparation is soluble and stable in alcohol, acetone, dioxane, pyridine and glacial acetic acid, and is insoluble in water, chloroform, sulfuric ether, benzol and toluol. The product contained 12.5 per cent of nitrogen, failed to give any test for proteins, and retained a bactericidal effect on gram-positive micro-organisms.

Hotchkiss and Dubos¹¹⁷ isolated from 100 gm. of crude material approximately 5 to 15 gm. of crystalline gramicidin, which crystallizes from acetone as characteristic spear-shaped, colorless platelets with a melting point of 228-230°C., found that 1 microgm. of gramicidin administered intraperitoneally protects a large percentage of mice infected intraperitoneally with 10,000 fatal doses of virulent Type I pneumococci, but 0.3 mg. administered intraperitoneally will kill mice, and smaller quantities will cause marked toxic reactions. Both tyrocidine and gramicidin are highly toxic when injected into the blood stream, but exhibit little toxicity when applied locally, as by the subcutaneous, intramuscular or intrapleural route. Christensen, Edwards and Piersma¹¹⁸ isolated the alcohol-soluble bactericidal material synthesized by *Bacillus brevis*. They are of the opinion that gramicidin is a polypeptide, and that its specific activity does not reside solely in these amino-acid residues.

Herrell and Heilman¹¹⁹ used the crude bactericidal substance obtained from a soil bacillus for bacteriological and clinical studies of gramicidin. Francis¹²⁰ believes that substances like gramicidin and penicillin can be used for the control and treatment of infections due to sulfonamide-resistant streptococci, and his experiments in vitro show that these streptococci are easily controlled by gramicidin. In their study of the effect of gramicidin administered orally to mice, Weinstein and Rammelkamp¹²¹ found it without effect on *Lactobacillus acidophilus*, whereas very small amounts had a bactericidal action on this bacillus in vitro. In evaluating the therapeutic activity of gramicidin one should not overlook the conclusions of Herrell and Brown,¹²² who note that recent observations concerning its hemolytic effect render it unsafe for general use. If its hemolytic property can be removed and its bacteriostatic effect preserved, an entirely new approach in the treatment of streptococcal infections may be developed.

In 1929, Fleming¹²³ found that a mold that appeared in laboratory bacterial cultures resembled *Penicillium rubrum*. The mold when grown on nutrient broth produced a very powerful antibacterial substance, which he named "penicillin." Its inhibiting action was very marked on pyogenic cocci and diphtheria bacilli, but was without action in colon, typhoid and influenza bacilli. A 1:800

dilution of the filtrate completely inhibited *Streptococcus pyogenes*, but did not inhibit the growth of *Haemophilus influenzae*.

Abraham et al.¹²⁴ have adopted as an arbitrary unit of antibacterial activity the amount of penicillin dissolved in 1 cc. of water, which gives the same inhibition as the standard. Material used in human therapeutic tests usually contains 40 to 50 units of penicillin per milligram. The administration of penicillin by mouth is complicated by the fact that it is rapidly destroyed by acid, and serious losses are to be expected in the stomach. These authors cite a case of local infection with hemolytic streptococci resistant to large doses of sulfanilamide and to moderate doses of sulfapyridine that improved greatly by treatment with penicillin. They report a case of corneal ulcer treated with a 1:5000 solution of penicillin in normal saline solution, with no irritation but improvement of the ulcer. Penicillin combines the two most desirable qualities of a chemotherapeutic agent—low toxicity to tissue cells and powerful bacteriostatic action. Its bacteriostatic action is in no way interfered with by body fluids or pus and only to a limited extent by large numbers of organisms. In local applications it has given promising results. Abraham et al. consider that enough evidence has been assembled to show that penicillin is an effective type of chemotherapeutic agent and possesses properties unknown in any other antibacterial substance heretofore described. Miles⁷⁰ says that penicillin is powerfully antibacterial. It has no observable toxic effect on phagocytes in antibacterial concentrations, and the antibacterial effect is not inhibited in the presence of organic matter. Its action is apparently bacteriostatic and thus permits the defenses of the body to take adequate action against the invader.

Although gramicidin and penicillin possess very interesting qualities and have unusually high bacterial activity, they have not been extensively studied. In fact, as yet it is only with difficulty that either can be obtained for investigational purposes. Obviously, both must be carefully observed, particularly with respect to any harmful qualities that they may possess, before they can be generally used for treating human wounds.

TISSUES AND TISSUE JUICES

In Carrel's¹²⁵ opinion the initiation of healing depends on the presence of leukocytes in wound tissue. Therefore he prepared leukocytic extracts from the blood of chickens one or two years of age and found that they possessed the power of increasing the multiplication of fibroblasts in vitro and stimulating the growth of tissues in vitro. The leukocytes are capable of bringing growth-activat-

ing substances to tissue cells. Even dead leukocytes set free substances that promote cell multiplication.

Carrell prepared aqueous extracts of inflamed connective tissue, which doubled the growth of new tissue, and embryonic juices from embryo chicks, which greatly stimulated the growth of fibroblasts in vitro. He believes that the power of tissue juice to cause growth is probably due to the ease with which its proteins can be transformed into peptides by tissue ferments, and that embryonic juices do not act as hormones but take part in the synthesis of protoplasm. The exact nature of the nitrogenous compounds present in these juices used by the epithelial and connective tissue cells in the building up of protoplasm is not known. Embryonic tissue juice loses its growth promoting effect after it is shaken for several hours or heated to 65°C for a few minutes. Attempts have been made to isolate the growth promoting substances from embryonic tissue juices, but fractionate precipitation by alcohol, acetone and other substances does not cause separation. The growth activating materials always remain with the protein precipitate.

Arey³³ points out that it is extremely difficult, if not impossible, to evaluate properly the effect of substances applied to wounds because of the possible concurrent effect of irritating stimuli. In this connection, Carrell¹²⁵ states that a slightly irritating dressing, dry gauze, turpentine or a few staphylococci will stimulate healing by irritating the wound, whereas the same substances have never been observed to produce an increase in the rate of multiplication of fibroblasts in vitro. Ruth¹²⁶ found that even injecting distilled water into the wounds of frogs stimulated the rate of epithelial proliferation.

A number of investigators have found that certain tissues and tissue juices promote tissue growth and thus stimulate wound healing. However, more extensive studies are needed in this field before tissues or tissue juices can be generally employed for treating wounds.

VITAMINS

Although a score or more of vitamins or vitaminlike substances have been studied with respect to their importance in the diet, only two, vitamins A and D, have received much attention as regards their influence on wound healing when applied locally.

Lohr,¹²⁷ Iost and Kochergin,¹²⁷ Hayashi,¹²⁷ Lohr and Treusch,¹²⁷ Horn and Sandor,¹²⁷ Zoltan,¹²⁷ and Drigalski¹²⁷ are all of the opinion that vitamins A and D applied locally stimulate wound healing. Sandor¹²⁷ concludes from his clinical experience that vitamin A alone expedites the reparative

process. McLaughlin¹²⁸ thinks that vitamin A is essential to cell growth, but Davson¹⁻⁷ is positive that vitamin A is not a factor in wound healing. Pyke¹²⁷ is of the opinion that vitamins A and D have no value in the treatment of wounds, and Brindaleone and Papper¹²⁹ believe that vitamin D is not effective in wound healing. Saita¹²⁰ applied irradiated ergosterol to wounds and healing proceeded half as fast.

Lauber and Rocholl¹²⁷ found that all vitamin salves were ineffective in healing experimental wounds on rabbits except for one which contained vitamin A and cholesterol. This accelerated healing by approximately 50 per cent. Drigalski¹²⁷ reports that guinea pig skin wounds treated with an ointment containing vitamin A healed better than when a vitamin A free ointment was applied, and believes that the epithelial protective vitamin A was the factor responsible for the better healing.

The number and extent of the investigations reported in the literature consulted are too limited to permit any final conclusion concerning the therapeutic activity of vitamins A and D when applied locally for the treatment of various types of lesions. However, the reports of the investigators cited above indicate that the majority believe that vitamins A and D applied locally to wounds stimulate granulation and epithelization.

COD LIVER OIL

It is not known when cod liver oil was first used for the treatment of wounds and burns, but the scientific literature of the past twenty five years contains many papers dealing with this subject. During the past seven or eight years Lohr¹²⁷ has conducted many investigations and has reported clinical observations with over 15,000 cases of wounds, ulcers and other skin lesions treated with cod liver oil. Kemmler,¹²⁷ Proto,¹²⁷ Lohr and Unger,¹²⁰ Drigalski,¹²⁷ Puestow, Poncher and Hammatt,¹³¹ and others were of the opinion that cod liver oil accelerated the healing of experimental wounds produced on rabbits and guinea pigs. Brindaleone and Papper¹²⁹ treated experimental wounds over the thoracic vertebrae of groups of 107 day-old rats, although more rapid healing was obtained in vitamin A deficient animals when cod liver oil was applied daily, such therapy had no effect on the rate of healing in normal animals. In other words, cod liver oil appeared to be of benefit only in the presence of generalized or local vitamin A deficiency. None of the treated animals developed infection, but 20 per cent of untreated animals became infected, and local application was more effective than oral administration of cod liver oil for promoting wound healing. In treating compound

fractures, especially under war conditions, Agostinelli¹³² recommends reduction of the fracture and careful cleansing and disinfecting of the wound, followed by daily application of cod-liver oil, which he believes prevents infection and stimulates rapid healing.

Several investigators have assembled data concerning the absorption of cod-liver oil by wounds. Helmer and Jansen,¹³³ Eddy and Howell,¹³⁴ Hume, Lucas and Smith,¹²⁷ Amrhein,¹²⁷ Astrowe and Morgan¹²⁷ and others have demonstrated that the vitamin A and D content of cod-liver oil can be absorbed through the unbroken skin. Zoltan,¹³⁵ Tennent,¹²⁷ Steel,¹²⁷ Lohr,¹²⁷ Iost and Kochergin,¹²⁷ Stevenson,¹²⁷ Brandaleone,¹³⁶ Ingram,¹³⁷ Hughes¹³⁸ and many others have reported that cod-liver oil promotes the granulation and epithelization of surgical and accidental wounds, ulcers and various types of lesions. In view of the outstanding results that have been obtained from the treatment of a wide variety of lesions with cod-liver oil, a question naturally arose as to the factor or factors that caused the stimulation of healing. Lohr,¹²⁷ Hayashi,¹²⁷ Lohr and Treusch,¹²⁷ Horn and Sandor,¹²⁷ Getz,¹³⁹ Kemmler,¹²⁷ Sandor¹²⁷ and others apparently believe that the therapeutic value of cod-liver oil for wound healing resides in its vitamin content. Pyke¹²⁷ thinks that its value for wound treatment is probably due to its rancidity, which he considers a possible source of "active oxygen." Recently Brandaleone and Papper¹²⁹ have commented on the influence of cod-liver oil fatty acids on wound healing, and Pels Leusden and Derlich¹⁴⁰ found that the removal of fatty acids from cod-liver oil reduced its bactericidal power.

Some investigators believe that cod-liver oil definitely inhibits the activity of organisms that infect wounds. Iost and Kochergin¹²⁷ think that cod-liver oil has great value in the treatment of wounds, owing to its inhibitory effect on certain types of pyogenic organisms. Tumanskiy and Yatsevich¹²⁷ claim that it inhibits the growth of both streptococci and staphylococci. Drigalski¹²⁷ found that cod-liver oil inhibited the bactericidal growth of gas and sporeforming bacteria, and Lohr¹²⁷ describes its value for treating local pyogenic infections. In a study of the bactericidal and sporicidal action of cod-liver oil, Pels Leusden and Derlich¹⁴⁰ killed such organisms as staphylococci, hemolytic streptococci and *B. anthracis* by suspending the organism in cod-liver oil. Campbell and Kieffer¹²⁷ report that cod-liver oil has a definite inhibitory and bactericidal action on virulent tubercle bacilli, lepra bacilli and *Eberth. typhosa*. Banyai¹⁴¹ recommends it for treating cutaneous and genitourinary tuberculous lesions. He accelerated healing following the removal of

tuberculous epididymes, testicles and kidneys by its local use.

Since it is difficult and often impossible to apply satisfactorily liquid cod-liver oil to lesions or wounds of ambulatory patients, cod-liver oil ointments have been developed for this purpose. Lohr,¹²⁷ who has made a careful study of the healing properties of cod-liver oil, seems to prefer it in an ointment. Other investigators such as Zuelzer,¹²⁷ Thiel,¹²⁷ Seiffert,¹²⁷ Arendt,¹²⁷ Lauber and Rocholl,¹²⁷ Jenico,¹²⁷ Schaer,¹²⁷ Horn and Sandor,¹²⁷ Drigalski,¹²⁷ Zoltan,¹²⁷ Ingram¹³⁷ and Lucke¹²⁷ also report using cod-liver oil ointments for healing wounds and other lesions. Cod-liver oil ointment was used during the Finnish War after excision of wounds, in conjunction with the closed plaster technic and was considered the method of choice.^{142, 143} In a study of the healing value of commercial cod-liver oil ointments Hardin¹⁴⁴ treated a series of 346 cases with wounds and burns. He reported that cod-liver oil is sterile and bactericidal, does not harm delicate tissues, exerts a beneficial systemic effect, reduces toxicity of pus, forms a protective nonirritating layer over the wound, and possesses a unique stimulating effect on the granulation and epithelization of tissues. In an eight-year study of the value of a 70 per cent cod-liver oil ointment in surgery, Aldrich¹⁴⁵ treated surgical lesions, varicose ulcers, decubitus ulcers, abrasions, minor burns, indolent burns and anorectal wounds and obtained prompt and satisfactory healing. Wolferman and Adams,¹⁴⁶ after extensive experience with cod-liver oil ointment in the treatment of industrial wounds, say that it is essentially bacteriostatic and sterile, and a stimulant to granulation, epithelization and wound healing.

SUMMARY

Literally thousands of materials have been suggested for promoting wound healing, but in this review of the literature attention has been centered on the influence on wound healing of diet, hydrogen-ion concentration, zinc peroxide, maggots and urea, sulfhydryl compounds, sulfonamides, gramicidin and penicillin, tissues and tissue juices, vitamins and cod-liver oil.

High-protein and high-polyvitamin diets are recommended. Investigators have shown that depletion of vitamin stores, especially that of vitamin C, interferes with wound healing; thus a carefully selected dietary is important in the treatment of accidental or surgical wounds, particularly if they are extensive.

Studies of the hydrogen-ion concentration of wounds have shown that a pH in excess of 7.0

favors healing and a pH of less than 7.0 is usually accompanied by pain. Hence a pH in excess of 7.0 enhances the patient's comfort and provides for rapid tissue growth.

Zinc peroxide has been found to be effective for killing pyogenic bacteria in wounds, but it leaves a zinc oxide residue and is likely to deteriorate in preparations stored for a long time before use.

During wars it has been observed that maggots promote the healing of wounds. Urea is one product of maggot excretions. Investigators agree that urea is valuable for promoting wound healing, particularly for removing debris and necrotic tissue, but concentrated solutions must be used. These may cause discomfort, and sedation is often necessary.

Sulphydryl compounds possess unusual value for stimulating tissue growth, but they also stimulate growth of organisms in wounds, and it is necessary to alternate sulphydryl treatment with other forms of medication.

The sulfonamides have unusually high bactericidal activity and are particularly effective in combating organisms frequently found in wounds. They are of great value to the surgeon, but they possess undesirable qualities and can cause serious damage unless administered under carefully supervised conditions.

Gramicidin and penicillin possess great bactericidal activity, but they have not been extensively studied clinically and must be carefully observed, particularly regarding any harmful qualities that they may possess, before they can be generally used for treating human wounds.

Investigators have found that certain tissues and tissue juices promote tissue growth and stimulate wound healing, but more extensive studies are needed in this field before these materials can be generally employed in the treatment of wounds.

Of the score or more of known vitamins, only two, vitamins A and D, have received much attention regarding their influence on wound healing when applied locally. Although the reported investigations are too limited to permit final conclusions, they show that these vitamins applied locally to wounds stimulate granulation and epithelization.

The literature contains numerous reports concerning the value of cod-liver oil for treating various types of wounds; but it seems likely that it promotes healing only in vitamin-A-deficient animals. Hence, the vitamin content is the likeliest active therapeutic agent. Some authors believe that cod-liver oil definitely inhibits the activity of organisms that infect wounds.

CASE 28501

PRESENTATION OF CASE

First admission. A fifty-nine-year-old woman was admitted because of severe colicky pain in the right lower quadrant.

The patient had been well until approximately nine hours prior to admission, when she was awakened by sudden, severe, knifelike pain in the right lower quadrant, which made her "double up and cry out." This radiated to the right lower flank and right upper quadrant and was followed by nausea, vomiting and occasional chilly sensations. She had never had a similar episode in the past. There was no urgency, frequency, dysuria, diarrhea or constipation. Her physician gave her morphine and nitroglycerin, which temporarily relieved the symptoms, but these soon recurred. The patient had been taking 8 gr. of thyroid daily for more than four years, although no definite diagnosis of hypothyroidism seemed to have been established. Her basal metabolic rate was -21 per cent, but her physician did not regard her as typically myxedematous. She was very sensitive to mushrooms.

Physical examination revealed a well-developed, rather obese woman in moderate distress, who complained of severe right-flank pain. Examination of the lungs was normal. The heart was somewhat enlarged to the left, and the sounds were very distant and muffled. A puffing systolic murmur was audible at the apex. There were tenderness and spasm in the right lower quadrant, maximum over an area just below McBurney's point, and there was tenderness at the right costovertebral angle.

The blood pressure was 96 systolic, 70 diastolic. The temperature was 99, the pulse 52, and the respirations 20.

Examination of the blood revealed a white-cell count of 8800. The urine was cloudy, amber and acid in reaction and had a specific gravity of 1.016; the sediment contained innumerable red cells, occasional white cells and epithelial cells. A blood Hinton test was negative. In a flat plate of the abdomen the kidneys were normal in size, shape and position. There was a triangular area of

calcification at the level of the right ischial spine. An intravenous pyelogram was normal on the left; on the right there was slight dilatation of the calyces, pelvis and ureter down to the area of calcification.

Soon after admission the right ureter was catheterized, and x-ray films showed that the stone had been carried upward approximately 3 or 4 cm. above its previous position. On the fourth day after admission the stone was removed. During hospitalization, she received a course of sulfathiazole by mouth, totaling 10 gm. in seven days. She was discharged on the eighth hospital day.

Final admission (nine days later). On the day after leaving the hospital she developed a slight fever and a feeling of weakness and lethargy and was thought possibly to have the gripe. She was started on sulfathiazole by mouth. Physicians were changed several times. This resulted only in the discontinuation of sulfathiazole and the substitution of sulfadiazine and later of sulfanilamide. During the eight days after discharge she received 125 gm. of sulfathiazole, 65 gm. of sulfadiazine and 2 gm. of sulfanilamide. One week after discharge she began to feel very weak and tended to sleep most of the time. At times she did not recognize people and did not respond well to stimulation.

Physical examination revealed a semistuporous, poorly co-operative, woman. There was slight rigidity of the neck. The pupils were equal and reacted well. The knee and ankle jerks were absent, and there was a questionable bilateral positive Babinski reflex.

The blood pressure was 65 systolic.

Examination of the blood revealed a hemoglobin of 11.8 gm. and a white-cell count of 12,600, with 91 per cent polymorphonuclears. The red cells and platelets appeared normal in the smear. The urine was light amber, acid in reaction, had a specific gravity of 1.008, gave a ++ test for albumin and showed a light-green sugar reaction; the sediment contained a rare red cell, 10 white cells and an occasional epithelial cell per high-power field. The nonprotein nitrogen of the serum was 48 mg. per 100 cc., the sugar 141 mg., and the sulfathiazole level 3.1 mg. (she received 15 gm. of sulfathiazole soon after admission). When repeated the next day, the nonprotein nitrogen was 32 mg. per 100 cc.; the bicarbonate was 23.4 milliequiv. per liter. The urine culture demonstrated a nonhemolytic streptococcus. The bleeding time was 2 minutes, and the clotting time 10 minutes. A lumbar puncture revealed an initial pressure of 90 mm. (water). The fluid was clear and contained 1 red cell per cubic millimeter. The total protein was 29 mg. and the sugar 92 mg.

per 100 cc.; the gold-sol curve was normal, and the spinal-fluid Wassermann was negative. An electrocardiogram showed a normal sinus rhythm with a rate of 85; there was evidence of slight left-axis deviation. The T waves were low in Leads 1 and 2, slightly inverted in Lead 3, and very low to biphasic in Lead 4. The urine was negative for follicle-stimulating hormone.

Two days after admission, it was recognized for the first time that the patient had been accustomed to taking thyroid extract and that during her recent illness none had been administered. She was started on $1\frac{1}{2}$ gr. of thyroid daily, and three days later seemed brighter, read the newspaper headlines understandingly and had no complaints. The blood pressure rose to 140 systolic, 90 diastolic. Despite her apparent improvement, eating became a problem for she refused to chew or swallow, although she did not choke on liquids. At times she seemed nauseated. On the sixteenth day her temperature rose to 100°F. and did so during the succeeding days. A urine examination revealed a ++ test for albumin, a specific gravity of 1.005 and negative reactions for sugar and diacetic acid; the sediment was loaded with white cells and amorphous material. When checked several days later, it was acid in reaction, had a specific gravity of 1.020, gave a + test for albumin and contained 2 red cells, 25 white cells and many bacteria per high-power field. The nonprotein nitrogen was 32 mg. per 100 cc., the bicarbonate 18.5 milliequiv. per liter, and the protein 6.7 gm. per 100 cc. Four days later, after being lifted into a chair, the patient immediately became pale, her eyes rolled back, the tongue rolled out of the mouth, and she fell forward and was pulseless. When returned to bed her color came back slowly; the pulse was 132, and the blood pressure 140 systolic, 90 diastolic. That evening the nurse found the patient lying on her back mumbling excitedly and incoherently. She did not respond when called, but when shaken gently she said, "Oh, I have had a nightmare." The next day she seemed mentally clearer but despondent and complained of extreme fatigue. The neurologic examination was negative. The patient died on the following day.

DIFFERENTIAL DIAGNOSIS

DR. MAURICE FREMONT-SMITH: The statement that this patient was very sensitive to mushrooms appears in the history only once.

DR. TRACY B. MALLORY: There was, however, a very clear manifestation of allergy. A soup even slightly flavored with mushrooms would regularly provoke symptoms.

DR. FREMONT-SMITH: But it does not come into the story again.

At the first admission the case is the easiest I have ever discussed. The patient had a stone, and the stone was located. It is worth commenting on two or three things at this point. She was fifty-nine years old and was well. She was taking thyroid; she had pain in the abdomen and red cells in the urine, and they made a diagnosis of renal stone. I want to point out one thing only: that pain in the abdomen and plenty of red cells in the urinary sediment do not necessarily mean stone. An acutely inflamed appendix that lies against the ureter can produce red cells in the urine in good quantity and one cannot therefore rest safely on the belief that there is a stone—it may be caused by the appendix. In this case, it is perfectly clear with the x-ray studies, the flank pain and the removal of the stone that she had a stone! We might think of some calcium upset such as hyperparathyroidism. If bilateral stones? Yes. If staghorn? Yes. If recurring stones? Yes. This stone is described as triangular. I think I am correct in saying that a triangular shape suggests an oxalate stone. We have no evidence for or against any hyperparathyroidism. It is something always to think about in relation to stone. She was discharged from the hospital apparently all right.

After having had a stone removed, the doctors thought she had mild urinary infection and they gave her sulfathiazole by mouth—not a very large amount, and probably not enough to be of significance in her later history.

I shall now discuss the second admission. The patient developed slight fever, probably owing to urinary infection, but she had lethargy, became very weak and tended to sleep most of the time. She also had slight rigidity of the neck. These symptoms are more than you would expect from mild urinary infection, and apparently the suggestion was made that she needed thyroid, which she was given. She improved very rapidly for a very short time, and then died.

I think it would be best to take the one positive finding we have to go on and start from there because it will open up the other lines of approach. "The urine was negative for follicle-stimulating hormone." This is put in in a very innocent way, but it is an important statement. It is absolutely abnormal for a fifty-nine-year-old woman to have a negative follicle-stimulating hormone test. At the menopause the level of the follicle-stimulating hormone goes up. The pituitary gland remains active, and the follicle-stimulating hormone remains elevated to good old age—some people say for the rest of the person's life. Furthermore, it stays up at high levels. When we say it is negative, we mean that the urine contains less than 10 mouse units per 100 cc., and this woman should

have had more than 10, and probably a great deal more than 10, mouse units per 100 cc. of urine.

There are various causes for an absence of follicle-stimulating hormone in a woman past the menopause, and one of these is a destruction of the basophilic cells in the pituitary gland by tumor or possibly by vascular thrombosis. In the first case, we have acromegaly. The tumor of the eosinophilic cells causes destruction of the basophilic cells, and these patients give negative tests for follicle-stimulating hormone. Then there are cases of so-called "panhypopituitarism"; some start at the time of labor following hemorrhage. Thrombosis of the vessels supplying the pituitary gland results, and these patients also have negative follicle-stimulating hormone tests.

I think we can say that panhypopituitarism is out. This woman was always well. She came in apparently a strong, well, woman. Patients with panhypopituitarism are weak, and they rarely live to be fifty-nine. They age very quickly and look very old but most of them die about forty. We have no evidence of acromegaly; there was no headache, and no changes in the visual fields are recorded. I think we can throw out acromegaly.

The other reasons for the absence of follicle-stimulating hormone concern the inhibition of the basophilic cells of the pituitary gland by other endocrines. One is an estrin-producing tumor, which puts the woman back where she was before the menopause. The tumor produces estrin, just as the active ovary gives off estrin, and the pituitary is inhibited and the level of the follicle-stimulating hormone comes down. The same is true of arrhenoblastomas and adrenocortical tumors, the latter producing a masculinizing hormone, which inhibits the pituitary. The arrhenoblastomas, according to Dr. Fuller Albright, produce a substance that inhibits the pituitary gland. Then there can also be lack of follicle-stimulating hormone from protein starvation, the anorexia nervosa group, and disappearance of the activity of the pituitary gland due to myxedema. In the absence of thyroid secretion the pituitary gland does not work properly, and the patient may have a negative test for follicle-stimulating hormone after the menopause.

That brings us to the question of myxedema. Could this woman have had myxedema? Apparently she had been given 8 gr. of thyroid. That may have been Burroughs and Wellcome thyroid, 1 gr. of which is equivalent to $\frac{1}{4}$ gr. of thyroid U.S.P. If so, she would have been getting a dose equivalent to 2 gr. I doubt very much if she could have stood 8 gr. of thyroid if she was myxedematous, although a normal person can stand it. There

are other facts. They gave her thyroid and she improved. Let me go back farther. They did not give thyroid and she went downhill; however, this does not happen that fast in myxedema. It takes a month for thyroxin to disintegrate in the body. A sudden state of thyroid deprivation after stopping thyroid therapy does not develop in twelve days. More than that, they say she was drowsy. She was definitely more than drowsy. She was psychologically inhibited, could not swallow and so forth. Something more than thyroid deprivation had happened to her. We get no help from the spinal-fluid findings. In myxedema the spinal fluid may be identical with that found in brain tumor — high protein and high pressure. Of course in this case the woman had been treated, and a well-treated case of myxedema has a normal spinal fluid. The spinal-fluid protein in myxedema will come down from as high as 242 mg. to 38 mg. after a month of adequate treatment. I do not know about the pressure, but I believe that also returns to normal. Here the spinal fluid does not help to make a diagnosis of myxedema. On the other hand, it does not rule out the diagnosis, because the woman had been treated.

Can we get any help as to the final outcome from the description of the heart situation? The patient is said to have had a big heart with blowing murmurs. Could she have had a coronary thrombosis with emboli in the brain? The electrocardiogram does not bear out a diagnosis of coronary thrombosis. She undoubtedly had coronary disease, but I do not believe that one can make a diagnosis of coronary thrombosis on that electrocardiogram.

I should be grateful to know if the patient had had a tooth out just before she came in. If so, I can make a very hypothetical picture that may be correct. If she had a tooth out she might very well have had a nonhemolytic streptococcus infection of the kidney, something that frequently follows tooth extraction.

DR. WILLIAM B. ROBBINS: She had had no tooth out.

DR. FREMONT-SMITH: All right, I was just going to say that she might have had subacute bacterial endocarditis on the same basis, with infarcts in the brain and other parts of the body. I do believe that this woman had an intracranial accident, and I am not satisfied to explain her symptoms and death on the basis of myxedema, which she may well have had. I believe she had an intracranial accident, and the most likely, on the basis of statistics, is thrombosis of a cerebral vessel. I shall leave that as my diagnosis, plus the question of myxedema.

DR MALLORY Have you anything to show that will help, Dr Holmes?

DR GEORGE W HOLMES The kidneys are normal in size and shape. Then I should like to point out these large gas filled loops of bowel. When a patient has stones there is an unusual amount of gas in the small bowel. Here is a beautiful demonstration of the stone picked up by the urologist's instrument.

DR JAMES B AYER The neurologic examinations, except the first one when she came in the second time, were always negative. The mental picture was one predominantly of lethargy. She was never in complete coma, but was lethargic. She fell asleep while talking, but on waking up she was quite well, never irrational. On one occasion she showed exceptional memory for recent and past events.

DR JURGEN RUESCH A prolonged disturbance of consciousness usually indicates a cerebral lesion, whereas lethargy may point to an involvement of the hypothalamus and the basal ganglions.

The fluctuating blood pressure may also indicate a lesion around the centers of the medulla oblongata. Confusion is not inconsistent with lesions in the upper cervical spine and the oblongata.

The possible cerebral lesion might have been produced by the three sulfonamides, which were given in rapid succession. In the literature, a number of cases have been described in which psychosis, disturbances of consciousness and confusion developed after use of these drugs. The majority of these patients recovered, a few, however, died. The pathology found consisted either of areas of softening or of multiple punctate hemorrhages.

In the present case I should expect a diffuse lesion in the brain.

DR STANLEY COBB I think perhaps we overlook the effect of the sulfonamides on the individual psychologically. Almost always there is some effect,—always a little confusion,—and I wonder if this is not a person especially susceptible to them. I believe we should be on the lookout for that effect and a bit more afraid of it than we are.

DR GEORGE G SMITH The thing that struck me about this patient was the peculiar type of lethargy. As Dr Ayer has said, she was not depressed when she woke up and not confused. She smiled and said just a few words and immediately went to sleep again. Along with that there was a marked depression in the blood pressure, which was around 60 systolic for a few days, as I remember it. The pus in the urine later on I think was accounted for by the fact that she was on constant drainage because she did not void. I expected that the mental condition would clear up immediately when we stopped the sulfathiazole. I believed at

first that she might have had a cerebrospinal meningitis, because she had had spinal anesthesia. A lumbar puncture showed no evidence of that. I soon realized that she was entirely beyond my crude methods of diagnosis and called in the neurologic experts.

CLINICAL DIAGNOSIS

Hypothyroidism?
Acute myocarditis?

DR FREMONT-SMITH'S DIAGNOSES

Cerebral thrombosis
Myxedema?

ANATOMICAL DIAGNOSES

Sulfonamide nephrosis
Hypertrophy of heart, slight
Aberrant thyroid tissue
Hurthle cell adenoma of aberrant thyroid
Encephalitis, toxic, slight.

PATHOLOGICAL DISCUSSION

DR MALLORY The anatomical findings in this case were very interesting, but I think they leave open the question whether they explain the clinical state and the demise. An outstanding finding at autopsy was in the kidneys. Dr Holmes has demonstrated that, in the film taken during the first entry when the patient had a stone, the size of both kidneys was perfectly normal. At the time of autopsy they were twice normal size, weighing over 200 gm, and were extremely swollen and very pale. On microscopic examination they showed a picture that we have begun to associate with reaction to the sulfonamide drugs. Our resident pathologist, Dr Maisel, working at Cornell last year in collaboration with Drs McSwain and Glenn,* studied the effects of prolonged administration of sulfonamide drugs in dogs. They have described an apparently specific lesion of the renal parenchyma, which is entirely independent of the precipitation of crystals in the tubules and pelvis. I am going to read Dr Maisel's description of the renal picture in this case, and then ask him to compare it with the experimental findings.

The sections of both kidneys are similar in appearance. No abnormality is recognized in the glomerular tufts. However, Bowman's space and the tubular system contain a hyaline glassy-blue protein material. Many of the tubular lining cells, particularly in the cortex, are poorly stained; the cell outlines are indistinguishable, and the nuclei are often pyknotic or absent. In many areas there is a break in the continuity of the tubular lining epithelium and basement membrane. Here the hyaline protein casts have been ex-

*Maisel D, McSwain B, and Glenn F. Lesions produced by sulfonamide drugs. *Proc Soc Exper Biol & Med* 49:715 '47 1942.

truded into the stroma. Inflammation is present in the stroma, frequently concentrated about the extruded protein casts, consisting of monocytes, epithelioid cells, multinucleated giant cells, a few lymphocytes and polymorphonuclears and a small number of plasma cells. Fibroblasts are present in some of these areas. A few of the collecting tubules contain many polymorphonuclears. No bacteria are recognized in sections stained by the Gram and Giemsa methods. About and in the walls of several veins, especially those of the peripelvic group, there are patchy areas of inflammation consisting of plasma cells, lymphocytes and a moderate number of polymorphonuclears. Mural thrombi are attached to the walls of veins overlying these foci of inflammation, and a few veins are completely thrombosed. The arteries appear normal.

DR. BERNARD MAISEL: It seems to me that there are several interesting things to learn from this case. This woman received relatively small doses of three different sulfonamides, thus making it difficult to incriminate any one. However, one is justified in saying that she reacted unfavorably to the sulfonamide group. This was manifest primarily in the psychobiology and in the kidneys. The mental picture has been discussed as fully as we are able to at present. As for the kidney changes, she developed albuminuria; and blood elements and transitional epithelial cells appeared in the urine. At no time were crystals of sulfonamide noted. Thus, renal injury developed without the presence of sulfonamide crystals and persisted several weeks after the drug administration was stopped. The nonprotein nitrogen did not exceed 48 mg. per 100 cc. and was usually lower than this. This does not point to glomerular damage, yet some change in glomerular filtration must have occurred, since protein and blood elements escaped to the urine.

Histologically, the changes resemble those noted in our animal studies. In the dogs, the tubules, particularly the proximal and distal convoluted tubules, were swollen and the lining cells were often necrotic. The lumens were filled with cellular debris and metachromatic, often glassy-blue, hyaline material, which we believe to be characteristic of a protein-sulfonamide combination. In some areas this material escaped from the tubules into the stroma. Here a granulomatous inflammation developed, and after approximately two and a half to three weeks, which coincides with the time interval in this case, multinucleated giant cells developed. The glomeruli in this case did not appear abnormal except for the blood elements in Bowman's space. However, in several of the experimental animals some were destroyed. In the dogs there was often an elevation of the urea nitrogen of the blood above 100 mg. per 100 cc., and a few developed blood-pressure elevations. In these animals it was interesting that, as the urea nitrogen

rose, the sulfonamide level rose, suggesting drug retention by damaged kidneys. Another interesting change in the kidneys of this case was the presence of inflammation about and in the walls of the veins, many of which were thrombosed. Often the thrombus was attached in an area of inflammation. The arteries in this case were normal, but our previous studies showed that an arteritis may occur. Finally, the bone marrow obtained from the lumbar vertebral bodies was moderately depressed, a condition that can be experimentally produced in the dog.

This case represents the first example in a human being that we have seen or heard of showing extensive granulomatous inflammation of the kidney as a result of the sulfonamide therapy. The injury obviously did not follow obstruction of the tubules by sulfonamide crystals.

DR. MALLORY: Dr. Maisel has permitted me to study many of his animal slides, and I agree entirely with him that the changes in this patient's kidneys are identical in type. Following his pointing out of the lesion to us, we have seen numerous kidneys with minor changes of this nature in patients who had received sulfonamides, but never anything approaching this grade of severity. It is of great interest that the total dosage was not great and that the levels which were attained in the blood stream were never particularly high. Possibly in that respect the history of allergy to mushrooms is important. She was an allergic person and may have had a hypersensitive response to comparatively small amounts of drugs.

Another interesting finding was a tumor behind the esophagus, which on microscopic examination caused us considerable trouble, because we could not decide at first whether it was a bit of aberrant thyroid tissue that had undergone degeneration into a fetal adenoma or whether it was a parathyroid adenoma. It was composed entirely of bright-red cells, so, if it was parathyroid tissue, it would have been the oxyphilous type and probably nonfunctioning. I think it is more probable, since we found a second nodule that was definitely an ectopic thyroid gland, that this first nodule was also of thyroid origin and represented a Hürthle-cell adenoma. That is merely an academic issue, however.

The brain showed nothing grossly. Dr. Kubik has been over it carefully microscopically. It is not normal, but that is about all he is willing to say about it. There is a slight but rather diffuse reaction in the cortex shown mostly by slight swelling and slight increase in the number of the microglial cells in the white matter. That is the only point on which he would definitely commit himself. He has seen somewhat similar pictures in cases with

uremia, and a variety of other disease states. It is the brain of a sick person, and that is about all one can say about it.

DR. ROBBINS: According to the time interval, the evidence of uremia was slight. It did not seem like uremia.

DR. MALLORY: The highest recorded nonprotein nitrogen was 48 mg., and it sank after that. It is hard to make out a picture of uremia and yet the kidneys were the major anatomical finding.

DR. FREMONT-SMITH: Was there anything in the thyroid to indicate myxedema?

DR. MALLORY: It seemed a little on the atrophic side. I cannot possibly make a diagnosis of myxedema from it. The pituitary gland was normal.

DR. ROBBINS: The thyroid was Burroughs and Wellcome, and after she was in the hospital she was given Armour's.

DR. OLIVER COPE: Three grains of thyroid a day ought to cause atrophy of the thyroid gland, atrophy of disuse. Dr. Mallory's description might well be accounted for on the basis of taking thyroid over a long period rather than true primary atrophy. I might also say that 90 per cent of the renal calculi occurring in hyperparathyroidism are unilateral. This condition should be excluded in any case of renal lithiasis.

DR. FULLER ALBRIGHT: I have seen several elderly patients with panhypopituitarism.

DR. FREMONT-SMITH: Was there any explanation of the negative test for follicle-stimulating hormone?

DR. MALLORY: Not unless she had myxedema. There was no tumor of the ovaries or adrenal glands.

DR. ROBBINS: I think she was always myxedematous. I had known the patient for years, and she was the myxedematous type—fat and heavy, with red cheeks.

DR. MALLORY: Since we have quite good proof of a severe sulfonamide reaction in one organ, it is not unreasonable to guess that the cerebral pathology might also be on the same basis. I do not believe we can go farther.

CASE 28502

PRESENTATION OF CASE

First admission. A fifty-seven-year-old man was admitted because of dyspnea, palpitation and loss of weight.

About three months prior to admission he began to suffer with exertional dyspnea, palpitation, evening ankle swelling and loss of weight and strength. His appetite increased; he was said to have become nervous and irritable and his eyes became more prominent. His voice seemed to have become somewhat hoarse.

Physical examination revealed a thin, nervous man with a moderate bilateral exophthalmos, and an obvious tremor of the hands. The thyroid gland was symmetrically enlarged. The heart was found to be enlarged, and the sounds were irregular in time and quality. A systolic murmur was audible at the apex. The neck veins were distended. The blood pressure was 135 systolic, 75 diastolic, and the cardiac rate was 120.

An x-ray film of the chest showed that the heart was considerably above normal in size. The greatest prominence of the heart shadow was in the region of the right auricle. There was no unusual prominence of the pulmonary conus or left auricle. There was a moderate tortuosity of the aorta. The lung fields were clear. The basal metabolic rate was repeatedly above +35 per cent. An electrocardiogram showed auricular fibrillation, with a rate of 110; the T waves were rather low in all leads.

After a course of Lugol's solution and rest the basal metabolic rate was +16 per cent. During hospitalization he received 3 gr. of quinidine daily, which slowed his cardiac rate slightly and produced a more regular rhythm. A bilateral subtotal thyroidectomy was done, and the removed glandular tissue showed hyperplasia. Following this his symptoms were markedly improved and he gained weight. He was discharged from the hospital on a daily dose of 10 drops of Lugol's solution and 3 grains of quinidine sulfate per day.

Second admission (two and a half years later). The patient was readmitted because of a moderate amount of dyspnea, palpitation on exertion and dull nonradiating precordial pain that had developed during the preceding eleven months. Several months previously on his own volition he had ceased taking the Lugol's solution and the quinidine sulfate.

Physical examination revealed essentially the same findings as noted in the previous admission except that only a nodule of thyroid tissue was felt in the right side of the neck at the clavicle. The blood pressure was 115 systolic, 75 diastolic. The basal metabolic rate was +40 per cent. An x-ray film of the chest revealed that the heart had increased only slightly since the previous examination.

He was again treated with Lugol's solution, and later digitalis was administered. Under local anesthesia the thyroid nodule was excised; histologically it resembled the previously removed thyroid tissue. After the operation, because of a persistent auricular fibrillation, the digitalis treatment was stopped and quinidine sulfate substituted, with a marked improvement in the cardiac rate and

rhythm. He was discharged from the hospital on the same drug routine as previously advised after the initial operation.

Final admission (ten years later, at the age of sixty-nine). Eleven months after discharge he noticed several brief attacks of substernal pressure, particularly after walking rapidly, and "spells" of palpitation. Physical examination in the Out Patient Department revealed only distant heart sounds and a rumbling systolic murmur maximum in the region of the xiphoid process. The cardiac rate was slow, and the rhythm regular. The blood pressure was 110 systolic, 62 diastolic, and the pulse rate was 72. The basal metabolic rate was $+18$ per cent. The symptoms continued without appreciable change in degree, and a physical examination a year later was remarkable only because a loud systolic murmur was then heard in the aortic area. No thrill was felt, and no diastolic murmur was audible. Six months later the murmur was described as hard and grinding, being audible over the entire precordium and replacing the first heart sound. The patient was able to engage in heavy work as a longshoreman despite the continuance of attacks of dyspnea and substernal pressure. Eight months prior to admission he noticed a progressively increased limitation of activity because of dyspnea and tightness across the chest. Both these symptoms disappeared after a few minutes of rest. On the day of admission, while at his usual work as a longshoreman, he felt a tightness in the chest. Sudden air hunger developed, and he collapsed.

Physical examination revealed an ashen pale man sweating profusely, sitting upright in bed and having extreme respiratory distress. He inhaled rapidly, and expirations were prolonged and labored. He was obviously quite restless. He could not speak, and responded only with grunts. The heart was somewhat enlarged to percussion. The heart sounds were of good quality. The cardiac rhythm was very irregular. A loud harsh systolic murmur was audible at the apex and transmitted with greatly diminished intensity to the left axilla. There was a soft blowing systolic murmur in the aortic area. Rales were prominent in both lungs. The abdomen was soft. The liver edge was felt about one fingerbreadth below the costal margin. There was no peripheral edema.

The blood pressure was 110 systolic, 60 diastolic. The temperature was 100.4°F ., the pulse 95, and the respirations 29.

The examination of the blood revealed a hemoglobin of 15.5 gm., a red-cell count of 5,300,000 and a white-cell count of 28,000, with 71 per cent polymorphonuclears. An electrocardiogram showed a regular cardiac rate of 140. The PR interval was

0.19 to 0.20 second; the QRS complex was notched; T_1 was inverted, with a low take-off of the ST segment in this lead, and T_2 was diphasic.

An electrocardiogram taken several hours later revealed a regular cardiac rate of 110. The PR interval was 0.20 second. The QRS complex was 0.10 second and was notched in Lead 2; T_1 and T_2 were diphasic; and there was evidence of a moderate left-axis deviation.

Despite the repeated administration of morphine, aminophyllin and oxygen and attempted, partially successful, phlebotomy, the patient became increasingly dyspneic and cyanotic and expired twelve hours after admission.

DIFFERENTIAL DIAGNOSIS

DR. PAUL D. WHITE: This case had a dramatic denouement that I learned about after the patient's death but which I did not guess during his life, and would not, I am sure, have thought of now. I shall tell you the reasoning I went through on the one occasion that I saw the patient in consultation. I do not remember the details of the post-mortem findings; I simply recall one important point, which was very surprising.

The heart was enlarged, the sounds irregular in time and quality, suggesting auricular fibrillation. There was a systolic murmur at the apex, and the neck veins were distended. We are led to wonder if this was a so-called "thyrotoxic heart" or merely a temporary effect of thyrotoxicosis on the heart or whether the thyrotoxicosis was superimposed on organic heart disease. Enlargement of the heart and distention of neck veins mean heart failure. There are likely to be other causes for this than thyrotoxicosis alone.

Frequently there is an increased pulmonary-conus shadow in thyrotoxicosis. The electrocardiographic finding of auricular fibrillation confirms the suspicion of that arrhythmia on physical examination; the statement about the T waves is unusual, for low T waves are characteristic of thyrotoxicosis. At one time we thought that since the T waves were flat in myxedema they should be high in thyrotoxicosis. Years ago Dr. Joseph Aub and I reported that there was no characteristic T wave in thyrotoxicosis; it tends to be low rather than high. Since then we have learned that high sympathetic tone depresses the T waves and that high vagus tone elevates them.

"During hospitalization he received 3 gr. of quinidine daily, which slowed his cardiac rate slightly and produced a more regular rhythm." That is not specific enough to point to the effect of the quinidine. Then there are remarks about less fibrillation. Fibrillation is a condition that is there or is not there. There may be a variation

in heart rate in fibrillation that is responsible for inaccurate reference to the degree of fibrillation. What one wants to know is whether there was persistence of fibrillation or a return to normal rhythm. This statement about a more regular rhythm is not good enough. Was there a return to normal rhythm? Was there a later electrocardiogram? There is no statement that the rhythm had returned to normal after the second admission.

The patient's condition at the time of his second admission suggests several different things. He may have had effort syndrome (neurocirculatory asthenia), which would give precordial oppression, dyspnea and palpitation. Angina pectoris would not ordinarily cause palpitation. Paroxysmal fibrillation usually does not occur at the same time as angina pectoris, they are two independent symptoms.

"... and a rumbling systolic murmur maximal in the region of the xiphoid process." That is an odd description. I do not know that I have ever heard a rumbling systolic murmur. It sounds as if it must have been a rough murmur or a grating murmur or mixed up with diastolic murmurs. Diastolic murmurs can certainly be rumbling but I do not think a systolic murmur can be. It was heard at the xiphoid process, low down. It is a little hard to decide about that at the present moment.

Then we have a statement that the rhythm was regular, years after paroxysmal fibrillation. Arrhythmias due to thyrotoxicosis can be controlled by thyroidectomy alone, or with the help of quinine and iodine. I should like to ask Dr. Lerman about the frequency of recurrence of thyrotoxicosis after thyroidectomy.

DR. TRACY B. MALLORY: There is a definite statement that when he came in at the time of the second admission he was fibrillating. When he left the hospital at that entry the rhythm was regular.

DR. WHITE: That is according to Hoyle. "A loud systolic murmur was then heard in the aortic area." There is no statement about the murmur that had been heard at the xiphoid process. I dare say that this is the same murmur that was described before as rumbling and heard at the lower end of the sternum. I expect that it had also been heard in the aortic area previously but not so specified. The "grinding" murmur heard over the entire precordium makes one think, of course, of an aortic stenosis murmur. Such a murmur varies a good deal in intensity according to the condition of the patient and tends to be very widespread over the precordium, more widely spread over the precordium than any other murmur. An aortic stenosis murmur is not heard so

well in the lung bases as elsewhere, for example, at the apex and lower end of the sternum. I suspect that this was the same murmur as that heard ten or twelve years previously. Underlying his condition the patient probably had an old aortic stenosis, which became more evident with increasing years. A calcareous aortic stenosis is likely, superimposed on some underlying aortic-valve disease. It is not necessary to diagnose an underlying rheumatic aortic valve lesion, but at any rate it is probable that he had had aortic stenosis for a long time. I have seen patients with aortic stenosis able to work very hard for many years when middle aged or older until rather abrupt heart failure set in, after which they did poorly. It says "heavy work as a longshoreman." He must have been a strong man.

He then showed both coronary and myocardial insufficiency. That may happen in the same person, but usually it is one or the other; either the myocardium fails or the coronary circulation fails, but one can have both fail almost simultaneously. Whether that took place prior to the final attack that brought him to the hospital, I am not sure, but while at work he had felt a "tightness across the chest."

There then occurred a sudden serious cardiovascular accident of some sort, not necessarily in the heart, and with it, apparently, left ventricular failure. What kind of accident could it have been? That is the problem we must try to decide.

We now have a different description of the physical examination than that previously given. He was desperately ill with a change in murmurs. There was no peripheral edema, no suggestion of right heart failure. The dyspnea increased. Possibly he had a pulmonary accident, of which I shall speak in a moment.

This change in murmurs is interesting. That often happens. Sometimes we have been confused or unable to diagnose aortic stenosis in these exercises because the patient was too sick to allow the hearing of the characteristic aortic stenosis murmur, which undoubtedly would have been heard, as in this case, when the patient was relatively well. The apical murmur evidently had increased. It is not likely that the aortic systolic murmur suddenly became louder at the apex as it failed at the base. It was more likely the result of some change elsewhere, most easily explained by the development of left ventricular dilatation, with superimposed mitral regurgitation. He did not have a high degree of shock so far as the blood pressure is concerned. The high white-cell count is somewhat against the first diagnosis that I should think of, namely, myocardial infarction. The electro-

cardiogram showed a regular cardiac rate of 140. We are not told whether the heart rhythm was normal. The record suggests that it may have been. At first the pulse rate had been 95, but by the time the electrocardiogram was taken the rate was 140. It might have been an abnormal rhythm but regular (for example, auricular flutter). However, the description is that of normal rhythm. "... T₁ was inverted, with a low take-off of the S-T segment in this lead. . . ." That often happens to T₁ or ST₁. One has to pay more attention to Leads 1 and 4 than to the other leads. The rhythm apparently remained regular. The electrocardiogram is not specific, although confirmatory, of coronary insufficiency, dependent usually on coronary heart disease but now and then also encountered in stenosis when there is a large heart and inadequate coronary circulation without actual myocardial infarction or even much of any coronary narrowing.

I should say that this patient died in left ventricular failure possibly due to coronary insufficiency. The underlying trouble I can state definitely was an old cured thyrotoxicosis, doubtless also calcific aortic stenosis, and quite likely coronary heart disease. We have no proof that patients with aortic stenosis can have this picture without coronary disease or coronary occlusion, but it is possible at seventy-one. Then the final fatal illness is interesting. There was no pain associated with this. There is a choice of several things, but there is about an even bet between painless myocardial infarction preceding heart failure and massive pulmonary embolism. In one way pulmonary embolism would explain the absence of pain and the marked dyspnea better than would myocardial infarction. I have seen painless myocardial infarction complicate a condition such as this in a patient with earlier angina pectoris. A less likely possibility is painless dissecting aortic aneurysm with heart failure. A rupture of the aorta of any other type and rupture of the aorta into the pulmonary artery would give different physical signs, the latter producing a continuous murmur like that of patency of the ductus arteriosus. That is not likely here but should be mentioned as a remote possibility. Pulmonary thrombosis or thrombosis elsewhere than in the heart or lungs, that is, cerebral or peripheral, is undiagnosable in the absence of any localizing evidence. Was there cardiac tamponade from hemopericardium due to rupture of heart and aorta? Probably not, since the blood pressure was too good and the veins were not engorged.

A PHYSICIAN: Is it possible that there was a rupture of one of the aortic cusps from calcareous stenosis?

DR. MALLORY: I do not believe we have ever seen that.

DR. JACOB LERMAN: I should like to comment on the initial onset of the disease. When I first saw the patient he had relatively recent onset of hyperthyroidism, and in the presence of a large heart and fibrillation we assumed that he had independent heart disease. Further studies verified the fact that he had coronary heart disease, and he eventually developed aortic stenosis.

Dr. White asked about recurrent thyrotoxicosis. The average incidence varies from 10 to 20 per cent following subtotal thyroidectomy, the smaller figure being in the group with more radical surgery and the larger in those with less radical surgery. This patient had recurrences; the first was removed, but he had another after the second operation. Fortunately that burned itself out and became normal after a long period of iodization.

DR. WHITE: Would the figure be as high as 20 per cent for recurrent thyrotoxicosis severe enough to require a second operation?

DR. LERMAN: Yes, if those cases controlled by iodine and rest are not included; of the latter, only about 5 per cent come back for operation.

DR. WHITE: One other point: the appearance of auricular fibrillation with each episode of thyrotoxicosis and its disappearance with relief of the toxic state is a very common finding. The auricular fibrillation may disappear even before operation through iodine alone and certainly post-operative four or five days after the temperature is normal. Many times it is recurrent when thyrotoxicosis makes itself manifest. It may or may not come back again after recovery.

CLINICAL DIAGNOSES

Arteriosclerotic heart disease.
Calcareous aortic stenosis?
Calcified annulus fibrosus?
Left ventricular failure, acute.
Pulmonary edema.
Coronary occlusion?

DR. WHITE'S DIAGNOSES

Recurrent thyrotoxicosis and auricular fibrillation (in past).
Aortic stenosis, marked.
Acute congestive heart failure, secondary to acute myocardial infarction, pulmonary embolism or some other factor.

ANATOMICAL DIAGNOSES

Calcareous aortic stenosis.
Calcification of mitral valve and chordae tendineae, with stenosis.
Rupture of mitral chordae tendineae, with terminal mitral insufficiency.
Hydrothorax.

Bronchopneumonia, slight, terminal.
Chronic pancreatitis, with fat necrosis.
Operative scar: thyroidectomy.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The post-mortem examination showed that this man did have severe valvular heart disease as Dr. White predicted. There was a long-standing calcareous aortic stenosis a little unusual in character. All the valve cusps were thickened, and on the sinus side of each cusp was a warty excrescence, each of which was densely calcified. The calcification extended up to the very margin. There was no interadherence at any of the commissures. It is very characteristic of rheumatic heart disease that the aortic cusps should become interadherent. So this absence of interadherence is a point against a rheumatic etiology. Many cases of aortic stenosis of this type show absolutely normal mitral valves. However, in this case the mitral valve was not normal. It, too, showed a moderate degree of stenosis. The circumference measured 6.5 cm., as compared with the normal of 10 cm. It was likewise extensively calcified. It was not quite the ordinary picture of rheumatic mitral stenosis, however, in that the leaflets were not interadherent and the calcification was more marked in the annulus than in the cusps themselves. The chordae tendineae attached to the mitral valve were likewise calcified, and the final sudden dramatic episode was quite clearly the result of sudden rupture of many of these chords attached to the posterior flap of the mitral valve. Half a dozen of the chords had broken sharply across so that the leaflet of the valve was without anchorage and was flapping loosely, at least in so far as its degree of calcification would permit. So there must have been a sudden and dramatic mitral insufficiency, which accounted for the terminal episode. There were no scars in the

myocardium. The coronary arteries were large and capacious; there was an occasional atheromatous plaque but nothing that appeared to narrow the lumens. Throughout the rest of the aorta the patient had far less arteriosclerosis than the average man of his age. It looked like the aorta of a patient of forty-five and he was seventy.

DR. WHITE: What did you find in the aorta? Was there any relation between the aortic-valve calcification and the sclerosis of the aorta itself?

DR. MALLORY: By and large, patients with calcareous aortic stenosis show less atheroma than other persons of their age. That is quite regularly true in the ascending aorta. In this case it was also true in the descending and abdominal portions. We have numerous sections of the myocardium. I can see nothing that to my eye constitutes conclusive evidence of rheumatic infection. I think in this case one has to leave the question of etiology open.

DR. WHITE: A very important point is that the abnormality of the electrocardiogram was due not to coronary heart disease but to aortic stenosis.

A PHYSICIAN: Have you made any observations relative to the degree of coronary sclerosis in these patients who have had hyperthyroidism? It has been my feeling that they seem to preserve their youth.

DR. MALLORY: I have not seen enough cases to have any strong personal opinion about it. There is a good deal in the literature, both clinical and experimental, to suggest that hyperthyroidism tends to retard the deposit of atheromatous material, whereas myxedema tends quite uniformly to increase it.

DR. WHITE: What Dr. Mallory has just said is about in accord with my experience. Certainly, arteriosclerosis is common with myxedema but I doubt if it is in thyrotoxic cases, since relatively few of them have angina pectoris.

THE SIGNIFICANCE OF THE RH FACTOR

BLOOD transfusion is usually a dramatically beneficial procedure. If it is accompanied or followed by a hemolytic reaction, however, it may be distressing both to the patient and to the physician. The commonly employed precaution of giving matched blood, usually of the homologous group, has made such reactions the exception rather than the rule. But even in intragroup transfusions, when cross matching has shown apparent compatibility, occasional reactions have occurred without apparent reason. One of the commonest causes for such reactions has now been disclosed by the work of Levine¹ and Wiener,² each of whom

demonstrated that red blood cells containing the so-called "Rh factor" (Rh+), present in 85 per cent of the white population, may be agglutinated by an anti-Rh agglutinin in the blood of a person lacking this factor in his red cells (Rh-). This agglutination results in a hemolytic reaction.

All physicians should be, and probably most of them are, aware of the following important facts, which were pointed out in a paper by Dr. L. K. Diamond on "Hemolytic Transfusion Reactions Due to the Rh Factor" in last week's issue of the *Journal*:

Rh- persons (those lacking the Rh factor in the red cells) may develop an agglutinin against the Rh factor by one or more transfusions of Rh+ blood. Subsequent transfusions of such blood may lead to serious hemolytic reactions.

Rh- women married to Rh+ men may develop this anti-Rh agglutinin during the gestation of an R+ fetus, since this blood factor is inherited as a dominant characteristic from the father. In such cases even the first transfusion with Rh+ blood may produce a serious, if not fatal, reaction. Such a transfusion tends to be common since, too often, the husband is used as the donor for the wife who requires blood. In addition, Levine³ has shown that an Rh+ fetus may be affected by the mother's anti-Rh agglutinin and develop all the signs of the serious intrauterine hemolytic disturbance commonly known as erythroblastosis foetalis.

Rh- women of child-bearing age given transfusions of Rh+ blood may be stimulated to the development of anti-Rh agglutinins that will produce erythroblastosis foetalis in infants of subsequent pregnancies.

The present-day increase in the number of blood banks has led to an increase in the number of transfusions administered. Theoretically, of every 1000 transfusions, 150 are given to Rh- recipients, and 85 per cent of them, or about 128, ordinarily receive Rh+ blood. This may stimulate the development of an antibody against the Rh factor, and after a relatively short interval another transfusion with Rh+ blood given to the same recipient is likely to cause a harmful reaction. In war injuries and in accident cases, multiple transfusions are often necessary, and the danger of transfusion reactions in Rh- recipients is greatly increased.

It therefore becomes imperative that Rh typing of blood be carried out, possibly on every member of the armed forces, and certainly on all patients requiring multiple transfusions or having had a previous transfusion, and on women of child-bearing age or those who have had infants with erythroblastosis foetalis. For the Rh-patient it has been shown repeatedly that only Rh-blood can be used with safety. It is commendable that in Boston an organization—the Blood Grouping Laboratory—has been formed by the Boston Lying-in Hospital, the Massachusetts Memorial Hospitals and the Children's Hospital for the express purpose of assisting other hospitals and individual physicians in properly handling cases of this type.

CHRISTMAS SEAL CAMPAIGN

THE war against tuberculosis, like the war against Hitler, finds the American people with victories won, but final victory yet to win. This is an enemy that never grants an armistice, and will never receive one. The Annual Christmas Seal Campaign of the National Tuberculosis Association, coming this year when we are deep in war, reminds us of a vital sector of the battle against disease.

Largely through the funds contributed in past years, the death rate from tuberculosis has been cut by 80 per cent since 1900. Since the last war, the development of x-ray examinations on a wide scale has aided materially in the discovery and early treatment of incipient tuberculosis. Special sanatoriums have been multiplied, and diagnostic clinics have been placed within the reach of all. Yet no drug has been found to cure the disease. It still causes more deaths in the age range of fifteen to forty than any other disease, being second only to accidents in the fatalities it brings, and the number of deaths at all ages is four or five times as great as the total of all other acute com-

municable diseases, except pneumonia and influenza.

In wartime, as is well known, the incidence of tuberculosis always increases: war adds to its forces the battalions of poor diet, lowered resistance and congestion of populations, all of which are predisposing to the disease. These evils are as yet largely confined to foreign countries, and preliminary figures for 1942 indicate that tuberculosis deaths in the United States will be the lowest on record. On the other hand, the American people have not so far been subjected to actual wartime conditions. The full impact of war on the campaign to control this disease will probably be felt during the coming year. This being so, those who purchase Christmas Seals will in a large sense be contributing to the national defense.

The campaign total has been set at \$8,000,000. Of the funds received, only 5 per cent will go to the National Tuberculosis Association for the maintenance of its headquarters and other running expenses; the rest will be allocated to states, counties and local communities. It will be used to carry on preventive work, to provide x-ray equipment and other diagnostic facilities and for kindred purposes. Special appeal is being made, as usual, for one-dollar and two-dollar contributions, which are within the reach of nearly all.

The American public has never failed to respond to appeals that arise from crises and threats of danger. To have a part, no matter how small, in the Christmas Seal Campaign is a privilege that millions will embrace, and that no one can in good conscience ignore.

OBITUARY

EDWIN EVERETT JACK

1863-1942

DR. EDWIN E. JACK, eminent ophthalmologist, was a Bostonian of the Bostonians by both birth and education. Entering from the Boston Latin School, he graduated from Harvard College and from the Harvard Medical School. In December, 1916, he was married to

Groom Denny, whose family roots in Boston were as deep as his own. This marriage was complementary to an unusual degree.

Early in his medical career he specialized in ophthalmology, and after serving for two years as house officer at the Massachusetts Eye and Ear Infirmary he became ophthalmologist to St. Elizabeth's Hospital and the Boston Dispensary; he was a member of the staffs of the Boston City Hospital, the Children's Hospital and the Eye and Ear Infirmary, of which institution he was made a consultant in 1926.

He was a member of The Country Club, the Harvard Club of Boston, the Thursday Evening Club of Brookline, the Massachusetts Medical Society, the American Medical Association, the New England Ophthalmological Society, of which he was past president, and the American Ophthalmological Society.

He never encumbered medical literature. His articles represented valuable and original contributions to his specialty. He owed his large practice not only to his knowledge and his operative skill but also to his gentleness and kindness to "all sorts and conditions of men" and women. These qualities won for him a high place in the family of "Beloved Physicians." Edwin Jack possessed and acquired many other admirable qualities that endeared him greatly to his colleagues and to his friends. He was a lover of the open spaces and traveled extensively. For many years he and his wife rarely missed a Boston Symphony Concert, and during the later years of his life, one of his chief joys was listening to fine music over the radio. He became a most appreciative and most reliable musical critic.

Someone has said, "The more I see of dogs, the less I think of men." Edwin Jack might well have made this remark, for his love of gentle and knowing canine friends was deep and was quickly reciprocated. Hidden by his gentleness were also the finest qualities of the soldier. After his retirement from practice he was obliged to face a series of serious illnesses, several of which involved painful operations and prolonged convalescence. He not only met them with complete bravery but achieved an optimism that approached gaiety. For several years he had known of the existence of the serious heart affliction that finally gave him release. He bore it placidly, mastering its discomforts, retaining his joy in life and in companionship and facing the future without dismay. "For unto every one that hath shall be given," and he was given the promised "abundance." If I read his life rightly, I realize that he gave in turn to medicine an Ideal of Conduct. To those of us who knew

him and loved him, he confirmed the saying of Ecclesiasticus, "A faithful friend is a strong defense . . . and is the medicine of life."

R. B. O.

MEDICAL EPONYM

SIMS'S POSITION

The position which James Marion Sims (1813-1883) described is not that which generally goes by his name at the present time, as will be seen from the following description, which appears in his article "On the Treatment of Vesico-Vaginal Fistula" in the *American Journal of the Medical Sciences* (N. S. 23:59-82, 1852). (By a curious misprint, although the pages from 1 to 60 are consecutively numbered, the page which should be 61 is 51, and the remaining pages of the volume are numbered consecutively from this point so that there are two series of pages numbered 51 to 60. The page reference of the following quotation should really be 69-92.)

In order to obtain a correct view of the vagina canal, I place the patient upon a table about 2½ by 4 feet, on her knees, with the nates elevated, and the head and shoulders depressed. The knees must be separated some 6 or 8 inches, the thighs at about right angles with the table, and the clothing all thoroughly loosened, so that there shall be no compression of the abdominal parietes. An assistant on each side lays a hand in the fold between the glutei muscles and the thigh, the ends of the fingers extending quite to the labia majora; then, by simultaneously pulling the nate upwards and outwards, the os externum opens, the pelvic and abdominal viscera all gravitate towards the epigastric region, the atmosphere enters the vagina, and there, pressing with a weight of 14 lbs. upon the square inch, soon stretches this canal out to its utmost limits affording an easy view of the os tincae, fistula, &c. To facilitate the exhibition of the parts, the assistant on the right side of the patient introduces into the vagina the lever speculum. . . .

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

RESOLUTIONS ON THE DEATH OF ALLEN GREENWOOD

WHEREAS, The death of Allen Greenwood, consultant in ophthalmology, has terminated an unusually long and continuous service to the Boston City Hospital (appointed ophthalmic and aural intern in 1889) with great distinction; and

WHEREAS, His passing has deprived us of a skillful and experienced teacher and consultant whose sympathetic understanding and generosity brought relief to so many; and

WHEREAS, His unselfish devotion to his professional duties will never be forgotten by his patients, nor his loyalty by his associates; be it therefore

RESOLVED, That we, the Senior Staff of the Boston City Hospital, express to the family of Allen Greenwood our sincere sympathy; and be it further

RESOLVED, That these resolutions be spread on the records of the Boston City Hospital and that a copy be sent to the family of Doctor Greenwood and a copy to the *New England Journal of Medicine* for publication therein.

CARMEL R. ALDEN, M.D., *Secretary*
Senior Staff, Boston City Hospital

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1941

HEMORRHAGE (*Concluded*)

Eight deaths from hemorrhage were associated with separated placenta.

The first case was that of a patient who had had four living children and when a little over eight months along in her fifth pregnancy had a blood pressure of 160 systolic, 100 diastolic, with the appearance of external bleeding. A diagnosis of separated placenta was made, and the patient was treated conservatively by transfusion and an abdominal binder. Forceps effected the delivery of a macerated fetus, the uterus was packed and a transfusion was given; but the patient died of hemorrhage fifty-five minutes later. This was a toxic separation of the placenta associated with intrapartum and post-partum hemorrhage. It is barely possible that hysterectomy, which should have been considered, might have prevented this catastrophe.

The second patient entered the hospital in severe shock due to premature separation of the placenta when approximately thirty-eight weeks pregnant, and died undelivered. She was treated conservatively by vaginal packing and the application of a Spanish windlass. Autopsy revealed premature separation of a normally implanted placenta. This case emphasizes the seriousness of separated placenta; there was no toxemia associated with this fatality, and the patient was given ideal treatment, in spite of which death occurred.

The third patient, with toxemia in her second pregnancy, had a spontaneous separation of a normally situated placenta at the beginning of her thirty-seventh week. Labor started spontaneously, and delivery was accomplished by low forceps. This was followed by excessive bleeding from the

uterus; glucose, plasma and 500 cc. of blood were given, but her blood pressure never returned to normal. This patient was given adequate treatment but died from shock and hemorrhage incident to separation of the placenta.

The fourth case was that of a primipara who began to bleed two weeks before term. A separated placenta was diagnosed, and the membranes were ruptured; but because the bleeding continued and the patient's condition became grave, an emergency cesarean section was performed. A stillborn infant was delivered, but the patient died three hours postoperatively. It is quite likely that this case should have been handled more conservatively from the start. If the vagina had been packed, a Spanish windlass applied and a transfusion given, the result might have been altered.

The fifth patient was a multipara at term in whom bleeding began when she was in labor; a separated placenta was diagnosed. The cervix was said to have been thick, and it was decided to perform a cesarean section. Transfusion was not given, and the patient died shortly after the operation. There seems to be no reason why, in this particular case, conservatism would not have been the better treatment.

The sixth case was that of a primipara who entered the hospital in shock three weeks before term. Her condition improved with treatment, and it was decided to do a cesarean section for separation of the placenta. A living baby was delivered, but the patient died three hours after the operation, autopsy revealing acute dilatation of the heart, probably brought on by the hemorrhage from the separated placenta. There is nothing in the handling of this case that can be criticized: when the patient is not in labor and a living child can be obtained, cesarean section is still considered an intelligent procedure.

The seventh patient had a cesarean section performed at term for complete separation of the placenta. The uterus failed to contract after the operation, and the patient expired, from post-partum hemorrhage two hours later. Again, one wonders why hysterectomy was not considered.

The history of the eighth case is not adequate. Separation of the placenta apparently occurred in a toxemic patient who presumably died shortly after a normal delivery.

In 5 cases, death was due to hemorrhage associated with placenta previa.

The first case was that of a patient who was admitted to the hospital with serious hemorrhage at eight months. A complete placenta previa was diagnosed and six transfusions were given, but the patient died a few hours after delivery. This death was probably due primarily to hemorrhage with

superimposed shock. There is little to criticize in the treatment of this case.

The second patient was a multipara with six living children, who began to stain when somewhat over eight months pregnant. She was kept in the hospital for three weeks, when a hemorrhage occurred, the cause of which was diagnosed as placenta previa. Although the patient was not in labor, cesarean section was done; a severe hemorrhage resulted, and she died on the operating table. No transfusion was given.

The third case was that of a multipara who began to bleed at the beginning of the last month of pregnancy. A diagnosis of placenta previa was made by x-ray, and a classical cesarean section was performed; the uterus failed to contract post-operatively, and death occurred five hours after delivery, in spite of transfusions. This patient was hospitalized for fifty days, and it is tragic that such careful prenatal care could not have averted this fatality. The question arises whether hysterectomy in the presence of continued bleeding might not have prevented death if the patient could have stood the operation.

The fourth patient entered the hospital at term, having had three separate attacks of vaginal bleeding before entry. She was not in labor, the fetal heart was audible, and the hemoglobin was 48 per cent. A diagnosis of placenta previa was made, and a cesarean section was performed; but death occurred one hour after delivery from profuse post-partum hemorrhage. It is suggested by the investigator that hysterectomy should have been considered.

The fifth patient, who had had no prenatal care, entered the hospital because of bleeding, the cause of which was diagnosed as complete placenta previa. A cesarean section was performed, and because the bleeding continued after the operation, the abdomen was reopened and the uterus removed. Death, however, occurred twenty minutes following the second operation.

The first of the 2 cases associated with placenta accreta was that of a patient at term on whom a cesarean section was done because of bleeding, a macerated fetus being delivered. Placenta previa was diagnosed at operation, after the placenta was found to occupy the entire lower segment of the uterus. It is probable that the placenta was an accreta since it could not be removed. Supracervical hysterectomy was done, but in spite of this the patient's condition became alarming because of the hemorrhage. Death occurred in spite of transfusion of blood and plasma a few hours after delivery.

The second case was that of a primipara who entered the hospital in labor, having had no prenatal care, and was delivered normally of a still-

born infant. She did not begin to bleed until after delivery of the placenta, which was not intact; the hemorrhage was profuse. The uterus was packed, but death occurred three hours after delivery. Autopsy revealed placenta accreta with uterine apoplexy. This patient was not transfused, nor was the accreta diagnosed until autopsy. Transfusion and intelligent diagnosis of the condition made by uterine examination might have permitted a hysterectomy and subsequent recovery.

Of the 31 patients who died because of hemorrhage, autopsies were performed in only 5.

This review of the cases with hemorrhage as a cause of maternal death reveals the interesting fact that placenta previa is a relatively uncommon cause, and separation of the placenta much commoner. Twenty-five years ago practically all cases of ante-partum bleeding were diagnosed as placenta previa; the existence of a separated placenta was seldom recognized. That two placenta accretas should be diagnosed as the cause of death in 1941 shows a greater appreciation of modern obstetric pathology.

There are few cases in this group in which operative interference or bungling obstetrics was the direct cause of the fatality. This is indeed gratifying. It is, however, unfortunate that many of these patients did not have the benefit of blood transfusion or at least the injection of plasma. The possibility of hysterectomy in certain of these cases needs to be emphasized because repeated transfusions and hysterectomy undoubtedly would have saved the lives of some of these patients.

DEATH

ELLSWORTH — SAMUEL W. ELLSWORTH, M.D., of Quincy, died November 27. He was in his seventy-third year.

He received his degree from Harvard Medical School in 1896 and had served on the staffs of the Quincy City Hospital, the Boston City Hospital and the Massachusetts Memorial Hospitals before specializing in x-ray work.

He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a brother and two sisters survive him.

WAR ACTIVITIES

CIVILIAN DEFENSE

PRACTICE SESSIONS FOR HOSPITALS

The following letter was recently forwarded to all deputy regional hospital heads of the Massachusetts Committee on Public Safety, copies being sent to all regional medical heads and all regional directors:

* * *

It has come to my attention on my trips around the State that the inclusion of hospitals in practice sessions of the mobile medical posts has been rather sadly neglected. To go on the assumption that "it cannot happen here" is simply closing one's eyes to something that one does not

want to see. It CAN happen here and we must be ready for it. Therefore, I urge you very strongly to see to it that you make the hospitals in your region acquainted with the fact that they are to participate in some of the practice sessions of the mobile medical units.

I assume of course that all the hospitals in your region that are to be used for emergency hospitals have already been organized for emergency service. This means that the organization of staffs and personnel has been completed, that the blackout system is completed and that plans have been made with the chief medical officers for the equal distribution of casualties so as not to overcrowd any one hospital.

I know it is difficult to hold these sessions and to mobilize the emergency hospital setup, nevertheless, it must be done to find out how the setup functions in each hospital and only in this way can confusion be avoided when the actual emergency arises. I have seen so much confusion in hospitals during a practice session that, if it were to take place during an actual emergency, it would be at the cost of lives. *This must be avoided.* The inconvenience of practice sessions now will be well worth the effort to assure the smoother functioning when the time comes.

Will you please see to it that the hospitals in your region and the chief medical officers are so notified. I should also like to have from you at your early convenience a report concerning the progress in this matter.

A WILLIAM REGGIO, Surgeon (R) USPHS
Director, Medical Division

Fall River (not New Bedford)	December 28

MISCELLANY

NOTE

At the fourteenth annual meeting of the New England Obstetrical and Gynecological Society, the following officers were elected: Dr Frank A. Pemberton, president; Dr Roy J. Heffernan, vice president; Dr Arthur F. G. Edgelow, secretary; Dr Frederick L. Good, treasurer; Dr Frederick J. Lynch, recorder; Dr Charles J. Kichham, chairman of Executive Committee; Dr John Fallon, chairman of Board of Governors; and Drs Bertram H. Buxton, Frederick L. Good, Adam P. Leighton, H. H. Rosenfield, Louis E. Phaneuf, Charles E. Mongan, John G. Walsh, Joseph W. O'Connor, Alonzo K. Paine, Foster S. Kellogg and Arthur Hertig, members of Executive Committee.

CORRESPONDENCE

DEPRIVATION OF LICENSE

To the Editor: This is to inform you that at a meeting of the Board of Registration in Medicine, held on Novem-

ber 20, 1942, the Board voted to revoke the license of Dr William P. Grovestein, of Scituate, Massachusetts, to practice medicine in this commonwealth because of gross misconduct in the practice of his profession, as shown by his conviction in court.

H. QUINBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

REPORT OF MEETING

NEW ENGLAND PATHOLOGICAL SOCIETY

The annual meeting of the New England Pathological Society was held at the Rhode Island Hospital on May 23, 1942. Dr B. Earle Clarke presided.

The first paper, Typhoid Fever, was presented by Drs Goodman, Zouraboff and Fagan, and Miss Annette Rivard. In July, 1938, an outbreak of typhoid fever occurred among a group of 335 disturbed female mental patients, all but one of whom had previously received antityphoid inoculations. The outbreak lasted seven months. In this period twenty (6 per cent) of the exposed patients became ill. Two died, and 10 of the convalescent patients became carriers. In addition, 9 asymptomatic carriers were finally isolated. Of the total of 19 carriers, 10 became chronic whereas 9 were temporary.

From a clinicopathological analysis of data accumulated over a period of almost four years, Dr Goodman concluded that antityphoid immunization does not afford complete protection to all exposed patients, but protects the majority and ameliorates the symptoms in many of the infected group (it has one undesirable feature—namely, that previously immunized individuals may become asymptomatic carriers, difficult to detect because of the absence of clinical evidence of infection), that multiple immunizations seem to increase the patient's sensitivity to the typhoid organism, rather than to augment his resistance to the infection and that a maximum agglutinin response within eight days (average three days) in previously immunized patients is usually associated with a mild clinical course (a maximum agglutinin response after eight days is associated with a prolonged or stormy illness, and this observation may prove to be an aid in prognosis in immunized patients).

Regarding carriers, he said that the terms chronic carrier and temporary carrier should be redefined and suggested that all arbitrary time limits between the two carrier states be abolished on the grounds that they are dangerously misleading and have no physiologic basis in fact. All patients whose gall bladders harbor the *Bacterium typhosum* are regarded as chronic carriers. They are not apt to be intermittent excretors and do not become negative spontaneously. Temporary carriers become negative spontaneously, but may excrete the bacilli for more than a year, with prolonged intervening phases of negativity.

Pre-existing or coexisting cholecystitis and cholelithiasis predispose to the development of the chronic typhoid carrier state. This explains the high incidence of chronic carriers in female patients over the age of forty years, and the tendency of the temporary carrier state to predominate among younger women. It also accounts for the discrepancy between their results and the reports of similar studies in mixed or male communities.

Dr Goodman said that cholecystectomy combined with appendectomy is the only procedure that can be used

tainly suggestive of an exogenous rather than an autogenous source for many of the [staphylococcal] infections.”

It has been my clinical experience that infection of the wounds in compound fractures of the skull is minimal during the first forty-eight hours after

the proper therapy of compound fractures of the long bones. The bacteriologic investigation noted above and a host of similar studies not included here answer this objection. Moreover, such work as that by Barnes⁸ and Trueta⁹ on wound infections emphasizes the relative unimportance of

*The figures in parentheses indicate the patients dying within twenty-four hours

the injury. I^{5, 6} have therefore repeatedly advocated postponement, for any necessary period up to forty-eight hours, of such major operative procedures as débridement. The postponement should last until after the patient is well out of surgical shock and until he is in an institution where personnel and equipment, including means for multiple blood transfusions, are available. I have always insisted, however, that as a corollary to this the first dressing must be one that only requires an absolute minimal handling of the wound and the débridement, when carried out, must be 100 per cent complete; one must actually excise all contaminated tissue without at the same time either spreading the contamination farther or causing tissue necrosis. Under such conditions, I⁷ have found that it has been possible, provided that those patients whose death, disability or difficulty with wound healing was directly traceable to technical errors arising out of failure to meet these requirements were eliminated, to treat 218 cases of compound fracture of the skull of all kinds with a corrected operative mortality of 9 per cent and a rate of postoperative sepsis of 8 per cent (Table 1). This series includes bullet and perforating wounds, fractures into the various air sinuses, cerebrospinal-fluid rhinorrhea, multiple injuries, associated meningeal hemorrhages and all degrees of brain injury.

Such a concept of bacterial contamination and treatment has been disputed on two main grounds. The first is that the method was not in accord with what was and is often still considered to be

bacterial contamination and the relative value of immobilization of the wound during the first forty-eight hours, whether débrided or not, as a means of preventing this contamination from developing into an infection.

The other criticism has arisen from the fact that no actual study of the bacteriologic contents of the wounds of compound fractures of the skull has been reported and that my theory as applied to this particular problem, although possibly true, had no bacteriologic facts to support it. I believe that the data presented herewith will answer this criticism, particularly since they conform with sufficient accuracy to the more extensive data concerning compound fractures of the long bones, as noted above.

Seventy patients with various types of compound fractures of the skull have had swabs taken from all depths of their wounds as well as from their noses, throats and ears and from two subcortical abscesses. The swabs were then plated for bacteriologic study. In addition, specimens of cerebrospinal fluid and blood were cultured and examined bacteriologically. The patients were divided as follows. In 10, the fracture was compounded not only through the skull but also into one of the paranasal air sinuses—usually the frontal; 6 of these patients died, and all were operated on and drained. In 7 with cerebrospinal rhinorrhea, 2 died. All but one were operated on; 3 cases were drained, and 3 were not, the fistula being closed by way of a transfrontal-flap craniotomy in the latter. Of 7 patients with

bullet wounds, 2 died; 2 were not operated on, 2 others were drained, and 3 were not drained, because the wounds healed by first intention. The bullet was removed in all but the patients who were not operated on, one of whom died of circulatory failure before his general condition war-

brain and 44 from the wound in general, making 112 in all. Because of variables in time and other factors, only cultures that were made from the wounds repay study. Fifty six of these were made on 52 patients. Pathogenic bacteria were grown from 38, or 67 per cent, of these cultures

ranted operation. The other is alive and well a year after his injury, although the bullet remains lodged in the base of his skull between the jugular bulb and the internal carotid artery. The arterio-venous fistula caused by its presence there has been closed by a ligation of the common carotid artery in the neck. Two patients with perforating wounds were operated on and survived, neither wound being drained. One of these patients had a previously unrecognized olfactory-groove meningioma at the time of his injury. This was removed after a subcortical abscess, which developed as the result of the improper treatment of the stab wound, had been healed up. Finally, there were 44 uncomplicated compound fractures. Four patients died, all following operation. Three others were not operated on. Eight patients, including 3 who died, had sepsis following operation. In 5 of these 8, including 2 of the deaths, the death and postoperative sepsis were directly traceable to improper therapy: 2 patients were operated on after the forty-eight-hour limit had passed, 2 had inadequate débridement, and in 1, tissue necrosis developed because of stitches that were too tight.

The cultures were grouped as follows: 1 from the ear, 4 each from the nose and throat, 2 from subcutaneous abscesses, 11 from the blood, 38 from the cerebrospinal fluid, 4 from the exposed calvarium, 4 from the dura, 4 from the wounds in the

All the bacteriologic work in this series was done under the direction of Dr. Robert N. Nye, assistant pathologist, and Miss Marion E. Lamb, bacteriologist, of the Mallory Institute of Pathology, Boston City Hospital. In accordance with the custom of the Bacteriology Laboratory, streptococci were reported only when they were of the pathogenic type. *Staph. aureus*, when reported, was also considered pathogenic, but *Staph. albus* even though reported, was considered nonpathogenic, as were *Aerobacter aerogenes*, diphtheroids, and "spreaders." Pneumococci and meningococci were both reported and considered to be pathogenic, of course. *Escherichia coli* was reported once. At autopsy, it was found that the patient had died of *Esch. coli* meningitis. No attempt was made to culture any anaerobes. Aerobic cultures (blood broth and blood-agar plates) were incubated seventy-two hours, and if no bacteria had grown by the end of that time, a report of "no growth" was made. It is not suggested, and I do not believe, that the wounds whose cultures showed "no growth" were sterile. I believe there can be no doubt that all the wounds contained bacteria. However, the contamination was so slight in many that the swab did not come in contact with any of the contaminants.

Of the 38 cultures of pathogenic bacteria, 29 (76 per cent) showed *Staph. aureus* only, 3 (8 per cent) *Str. haemolyticus* only, and 5 (13 per cent)

a mixture of both (Table 2). Meningococci were grown from only 1 culture. If these figures are broken down still further, particularly in relation to the time elapsing between the infliction and swabbing of the wound, certain other significant data are apparent. Thirty-one wounds were swabbed within twenty-four hours or less of the receipt of injury. Of this group, 17 (55 per cent) showed pathogenic bacteria. No pure cultures of hemolytic streptococci were grown, and only 2 of mixed hemolytic streptococci and *Staph. aureus*. The remaining 15 all showed pure *Staph. aureus*. Forty-four wounds were forty-eight hours old or less when cultured. Twenty-six (66 per cent) grew pathogenic bacteria. Of these, 1 (4 per cent) grew *Str. haemolyticus*, and 4 (15 per cent) a mixture of this organism and *Staph. aureus*. The remaining 21 showed pure *Staph. aureus*. Twelve wounds were cultured when they were over forty-eight hours old. Eleven, or 91 per cent, contained culturable pathogenic bacteria. Thus, the percentage of compound fractures of the skull that contained cultural pathogenic bacteria within the wounds rose from 55 in the first twenty-four hours through 66 in the first forty-eight hours to 91 after forty-eight hours had elapsed between the receipt of the wound and its swabbing for culture. The conclusion seems inescapable from these figures that the rate of contamination of such wounds is essentially stationary for forty-eight hours after their infliction, but that thereafter it rises rapidly to the neighborhood of 100 per cent.

There were 7 patients from whose wounds hemolytic streptococci were cultured eight times. Three of the cultures were pure, and the rest were mixed with *Staph. aureus* alone twice and with both that and *Staph. albus* three times. Three wounds were cultured at operation, and only 2 of these within twenty-four hours of the infliction of the wound. One of the latter patients had a very extensive compound fracture of the frontal bone, with practically complete destruction of the posterior wall of one frontal sinus and a wide-open communication between the nose and the meningeal spaces. The other had a simple compound fracture. The wound had been treated only by covering with a sterile gauze pad. This is the sole case in which the streptococcus might have been introduced at the time the wound was made. The patient was struck about the head and face by an assailant who used an iron bar. The skull was fractured in the right parietal and left temporal regions. Another culture, made from this wound fourteen days postoperatively, was also positive for hemolytic streptococci. This patient survived. In the third patient and the 4 succeeding ones, all the wounds were cultured forty-eight or more hours after infliction. The third patient was an-

other whose fracture was compounded not only externally but also into a frontal sinus. He was not brought to the hospital until twenty-four hours after he had been injured. The wound was cultured forty-eight and débrided fifty-five hours after infliction. Meningitis was already present when the débridement was performed. This patient died. The other cultures were made two, two, ten and twelve days after infliction, or one, one, nine and eight days after operation. In view of the time that elapsed between the injury and the postoperative culture, there was ample opportunity for implantation of streptococci into these last five wounds after their infliction and before they had been cultured or débrided. Of these 5 patients, 4 died, 2, partly at least, because débridement was postponed for fifty-five hours in one case and was not done at all in the other, with the result that meningitis supervened in the first and a cortical abscess in the second. Death in the other 2 cases was from meningitis, despite the fact that all technical requirements had been met. The fifth patient survived in spite of a complicating meningitis. The technic used was satisfactory. No throat or nose cultures were made from any of these 7 patients.

In 1 patient, meningococci were cultured from the wound seven days after its infliction and one day after operation. The fracture in this case was compounded through the frontal bone and also into one frontal sinus. At operation, six days after the injury, the wound was irrigated. The patient died of meningitis and a frontal-lobe abscess. The meningococcus certainly originated in the nose and was spread by the irrigation.

Pneumococci were cultured from 3 patients. All had fractures compounded into the nose, 1 by way of one frontal sinus and the other 2 by way of the cribriform plate, both the latter being accompanied by cerebrospinal rhinorrhea. The first patient was not operated on, and the pneumococcus was cultured from the cerebrospinal fluid ten days after the injury and in the presence of a meningitis. The second case was similar in that no operation was performed, but the bacterium was cultured from the cerebrospinal fluid four days after the injury. A positive blood culture was obtained in this case at the same time. Sulfapyridine had been given by mouth from the start. Both these patients died. In the third patient, the cerebrospinal-fluid fistula was closed within twenty-four hours of the injury by way of a transfrontal bone-flap operation. Just previous to this, a culture of the nose had proved positive for pneumococci. The wound healed by first intention, and the patient recovered. None of the sulfonamide group of drugs were used in this case.

There were 3 deaths among the patients from whose wounds *Staph. aureus* was grown. All were directly traceable to errors in technic. In 1 case, meningitis followed forcible removal of a Mosher cone-shaped copper-wire drain about three weeks after operation for a compound fracture of the frontal bone that involved one frontal sinus; another patient died of *Esch. coli* meningitis following a débridement that was not done for sixty hours after the accident; this patient was given sulfapyridine by mouth. In the third patient, who had a bullet wound, the débridement had to be postponed for forty-eight hours because of the patient's general condition. Sulfapyridine was given by mouth and sulfanilamide put in the wound from the first, and the wound was closed at operation. The patient died from meningitis. Three other patients recovered but had sepsis in their operative wounds. In 2 cases, no cause for the sepsis could be found in the technic, but in the third,—a perforating wound, in which débridement was not done,—a cortical abscess followed.

There were 20 wounds in which the cultures were reported as showing either no growth or *Staph. albus*. Three of these patients died—all in the "no growth" group. Two wounds were compound fractures of the frontal bone, with extension into one frontal sinus. One patient, who was not operated on, died of pneumococcal meningitis, and the other died four days after operation of a meningitis whose cause was not identified. The third patient, with a bullet wound, died of circulatory failure before he could be operated on. Four other patients, who recovered, had sepsis or wounds that failed to heal by first intention. The sepsis was traceable to technical errors in every case. One, with a compound fracture of the frontal bone and involvement of the frontal sinuses, who was not operated on until six days after injury, developed a secondary frontal subcortical abscess, which later had to be drained. Another, with an uncomplicated compound fracture, was not brought to the hospital until sixty hours after injury, and although the wound was partially débrided two hours later, it was considered better judgment to pack the wound and allow it to heal by second intention rather than to close it at once. The third patient—a similar case to the last—was not brought to the hospital for five days. No operation was performed, the wound being merely packed wide open. The last case was also an uncomplicated compound fracture in which it was decided to substitute chemotherapy for surgery—sulfapyridine was administered by mouth and sulfanilamide put in the wound. The wound granulated but refused to heal completely until, at the end of two weeks, exploration disclosed a "rock" of sul-

fanilamide. This was removed, after which the wound healed promptly. There were no deaths or sepsis among the 9 patients from whose wounds cultures yielded *Staph. albus* only.

DISCUSSION

It appears from this material that the degree of culturable contamination of the wounds of compound fractures of the skull varies from 55 to 66 per cent during the first forty-eight hours after infliction, provided the wound is not "massaged" during that period. The rise during the second twenty-four-hour period is statistically minimal, and it probably makes little difference at what time during this forty-eight-hour period the débridement is done, provided it is 100 per cent complete. If these requirements are fulfilled, and particularly if inhibition of further growth of bacteria is aided by proper chemotherapy, postoperative infection of such wounds should be reduced to something closely approximating that seen after uncontaminated surgical wounds anywhere in the body. The contention that pathogenic hemolytic streptococci are not deposited in the wound at the time of its infliction, as advanced by Hare and Willis³ and others in compound fractures of the long bones, must be considered to hold true also in compound fractures of the skull with one exception. This refers to fractures that involve the paranasal sinuses and applies not only to hemolytic streptococci but also to meningococci and pneumococci. Except for multiple small perforating wounds, with many fragments of foreign bodies scattered throughout the substance of the brain, I see no reason so far as this experience goes, to differentiate either bacteriologically or therapeutically bullet wounds from other types of compound fractures of the skull. This is in general accord with recent experience with compound fractures of the long bones as cited by Trueta⁹ and others. Moreover, this evidence supports the contention of Trueta and of Barnes⁸ that immobilization of the wound is the critical factor if, for immobilization, one means a "minimum of handling at the first dressing of the wound" and until the débridement is done. It must be evident that this dictum is much more important and more in accord with the established facts than any shibboleth that is based on tradition. There is no "golden six-hour interval" in which surgery of compound fractures of any bone whether long or flat must be practiced. If the bacteria contaminating a wound are "stirred with a spoon" or the tissues contaminated by these bacteria are "massaged," a thirty-minute interval between infliction and débridement is too long to wait before one deals with the infection that has been conjured up

out of what was only a contamination. If the contamination is recognized for what it actually is and treated with the respect it merits, infection can be prevented from developing by a proper débridement carried out at any time within the first forty-eight hours after infliction of the wound, provided the patient is safely out of surgical shock and in a properly equipped and staffed hospital.

SUMMARY

A report of 112 cultures made from 70 patients with varying types of compound fractures of the skull is presented.

Fifty-six wound cultures were taken in 52 cases. The incidence of infection in the wounds of these compound fractures of the skull was 55 per cent during the first twenty-four hours, 66 per cent during the first forty-eight hours, and 91 per cent after forty-eight hours had elapsed between infliction and swabbing of the wound.

Pathogenic hemolytic streptococci were grown from the wounds of only 7 patients, in only 1 of whom there was evidence that the contamination could reasonably have taken place at the time of infliction of the wound.

These results conform in general to those obtained from the study of certain series of wounds in other parts of the body received in military action, in the course of air-raids and in civil life.

They emphasize the value of immobility of the wound or its equivalent in all compound fractures as a means of preventing contamination from becoming infection, and the lack of significance of the local growth of bacteria as the cause of this change.

PLASMA PROTHROMBIN AND LIVER FUNCTION DURING SULFONAMIDE THERAPY*

ISRAEL KAPNICK, M.D.,† JOHN D. STEWART, M.D.,‡ AND CHAMP LYONS, M.D.§

BOSTON

THERE have been described two types of injury to the liver resulting from therapy with the sulfonamides. Jaundice and signs of diminished hepatic function may accompany the acute hemolytic crises that occasionally occur following the administration of these drugs. Secondly, a primary hepatitis may result as a direct toxic effect of the chosen drug on the liver cells.

The acute hemolytic crisis with a rapidly progressive anemia may come on at any time following the onset of drug administration, and usually occurs within three to five days. Wood¹ found the anemia to occur only in febrile patients. The hemoglobin may fall rapidly to 20 to 30 per cent of normal, and this is accompanied by a rise in temperature, polymorphonuclear leukocytosis, reticulocytosis and an increase in immature cells, with evidence of hyperactivity of the hematopoietic system. Hemoglobinuria may occur.² In some

cases this is accompanied by jaundice, with evidence of hepatitis and diminished hepatic function. The hepatitis may be mild and clear up rapidly after the drug is stopped. The severe cases may go on to acute yellow atrophy and death. The presence of jaundice in hemolytic anemia has been ascribed mainly to the hemolytic process, but direct liver damage may coexist with it.³

There have been a number of reports indicating an apparent primary acute toxic hepatitis with jaundice and decreased liver function during or subsequent to sulfonamide therapy, with several deaths. The importance and the serious nature of this complication are indicated by the fact that nearly all the fatalities resulting from the sulfonamide drugs have been due to agranulocytosis, toxic hepatitis or hemolytic anemia. Hageman and Blake⁴ noted 1 case of toxic hepatitis with recovery in a group of 114 patients receiving sulfanilamide, and Bannick, Brown and Foster⁵ reported 2 deaths. Cline⁶ reported autopsy findings of acute yellow atrophy following the administration of 45 gm. of sulfanilamide. Saphirstein⁷ had a severe but nonfatal case of toxic hepatitis following the use of this drug, with an associated der-

matitis which was exfoliative in character. This has been seen to accompany the hepatitis in several other cases reported in the literature. Garvin⁸ reported 5 cases with 1 death, and Berger and Applebaum⁹ reported autopsy findings of subacute liver atrophy following sulfanilamide. Other cases of toxic hepatitis have been reported by Ottenberg,¹⁰ Fitzgibbon and Silver,¹¹ Gertler¹² and Russell.¹³ A fatal case reported by Tragerman and Goto¹⁴ showed degeneration of the liver cells. Greene and Hotz¹⁵ mention 4 cases of hepatitis with 2 deaths, and found an increase in the sulfanilamide level in the liver in a patient with hepatitis. Spring and Bernstein¹⁶ reported 2 cases in which there was a coexistence of toxic hepatitis with acute hemolytic anemia and renal damage following sulfanilamide.

Long, Haviland, Edwards and Bliss¹⁷ found that the incidence of toxic hepatitis, as indicated by jaundice without anemia and a definite impairment of liver function, occurred in 0.6 per cent of 1000 hospitalized adults receiving sulfanilamide therapy. Many other authors have noted mild attacks of jaundice without anemia, which usually subsided rapidly on discontinuation of the drug. The incidence of these occasional complications is not inappreciable. Jaundice appears to be commoner after sulfanilamide than after other drugs of the sulfonamide series.

Hepatitis may occur early or late in the course of therapy, and may even first be observed up to six days after the drug has been discontinued. In most of the cases reported the dosage has not been particularly large, and in almost all cases was below 50 gm. The hepatitis may take the form of toxic necrosis or of acute yellow atrophy. Jaundice, hepatomegaly, splenomegaly and ascites may occur. There is usually an immediate direct van den Bergh reaction, increased urobilinogen in the urine and decreased hepatic function. Often a high temperature and leukocytosis occur with the hepatitis, and the patient is acutely ill. In mild cases the prognosis is usually good if the drug is immediately stopped, fluids forced and supportive treatment instituted. However, the hepatitis may progress in spite of the discontinuance of the drug, as illustrated by 2 of the cases presented by Garvin.⁸

MATERIALS AND METHODS

All patients studied in the present series were on the surgical wards of the Massachusetts General Hospital in the spring and summer of 1941, and had infections of the average type found on a general surgical service. These included cellulitis, abscess, carbuncle, thrombophlebitis, bacteremia, urinary infection, osteomyelitis, acute pulmonary and pelvic infections, and ulcer. About half the patients were acutely ill with marked febrile reac-

tions; the remainder had more chronic, less virulent infections. The drugs used were sulfanilamide, sulfapyridine, sulfathiazole and sulfadiazine. The dosages varied from as little as 3 to 8 or 9 gm. per day.

The liver-function tests selected for study were the bromsulfalein excretion, the van den Bergh reaction and the prothrombin time. The Quick¹⁸ technic was used for this latter test.

It has been pointed out that reduction in the plasma-prothrombin level may be an early and very sensitive indication of decline in hepatic reserve.¹⁹ Wilson²⁰ found a close correlation between the level of plasma prothrombin and the hippuric acid liver-function test. In patients with liver damage these two were more sensitive measures of hepatic damage than any other liver-function test. However, in any toxic reaction to the liver it is possible that the different functions of this organ may be affected to a varying extent. One function may show severe incompetence, while another is completely unaffected.

The tests in our series were carried out before the drug was begun, and at intervals until several days after the drug was discontinued.

DATA

Sixty-eight patients in all were studied, and of these 14, or 21 per cent, showed an appreciable increase in prothrombin time during the course of chemotherapy. Only a few of the latter showed changes in bromsulfalein excretion or in the van den Bergh reaction. No patient showed changes in these latter two without, in addition, showing a fall in the level of plasma prothrombin.

The cases with significant increases in prothrombin time are abstracted below.

CASE REPORTS

CASE 1. J. P., a 39-year-old Finnish housewife with known biliary cirrhosis of 2 years' duration, was admitted for study of generalized xanthomatosis of 2 months' duration. She had been under treatment with parenteral and oral vitamin K for 9 months because of a prolonged prothrombin time. A biopsy of one of the xanthomatous nodules was performed, and 6 days later the patient developed a cellulitis and erysipelas, with redness, pain, lymphadenitis, a temperature of 103.4°F. and a white-cell count of 19,100. Cultures of the leg showed a virulent beta hemolytic streptococcus (Group A, Lancefield) and coagulase-positive *Staphylococcus aureus*. In view of the liver damage it was thought that chemotherapy was inadvisable, but the patient developed a chill and extension of the clinical signs of infection. The prothrombin time was 21 seconds (21 seconds*) and the van den Bergh reaction was 5.4 mg. per 100 cc. The patient was given 6 gm. of sulfanilamide initially, then 1 gm. every 4 hours. She was also given 32,000 units of scarlet-fever antitoxin and an immune transfusion because of the absence of opsonic antibodies from the blood. The infection improved rapidly but on the seventh day of chemotherapy

*All figures in parentheses indicate the normal prothrombin time.

the prothrombin time was 85 seconds (23 seconds) and the van den Bergh reaction was 6 mg. per 100 cc. The chemotherapy was stopped and intravenous vitamin K was given. Within 24 hours the prothrombin time was normal.

CASE 2. L. T., a 64-year-old Negress, had a radical mastectomy for adenocarcinoma. Postoperatively she developed a staphylococcal infection of the wound, which was drained. She appeared to be doing well but suddenly developed erysipelas, with a temperature of 105°F. and redness and an erysipeloid reaction about the wound. The prothrombin time and van den Bergh and bromsulfalein tests were all normal. The patient was given 4 gm. of sulfapyridine initially, then 1 gm. every 4 hours. She also received 32,000 units of scarlet-fever antitoxin and an immune transfusion. A blood culture showed two colonies per cubic centimeter of beta hemolytic streptococcus (Group A). The temperature returned to normal in 48 hours. On the 3rd day of chemotherapy the prothrombin time was 29 seconds (23 seconds), the van den Bergh reaction was negative, and the bromsulfalein test showed a 5 per cent retention. On the 7th day of chemotherapy the prothrombin time was 32 seconds (23 seconds), the van den Bergh reaction was negative, and the bromsulfalein test showed a 12 per cent retention. The drug was discontinued, and on the 10th day all the tests were normal.

CASE 3. M. D., a 38-year-old housewife, was admitted for repair of a ureterovaginal fistula. At operation the ureter was implanted into the dome of the bladder and sulfanilamide powder was placed in the wound. On the 3rd postoperative day the patient developed pyelitis. A blood culture taken at this time yielded *Escherichia coli*. The prothrombin, van den Bergh and bromsulfalein determinations were all normal. Sulfapyridine was given in a dosage sufficient to maintain a blood level of between 10 and 12 mg. per 100 cc. On the 4th day of chemotherapy the prothrombin time was 38 seconds (23 seconds), the van den Bergh reaction was negative, and the bromsulfalein retention was 8 per cent. On the 5th day of chemotherapy the prothrombin time was 38 seconds (23 seconds). The chemotherapy was omitted and Hykinnone was given parenterally. Twenty-four hours later the prothrombin time was normal. Four days later the bromsulfalein retention and the van den Bergh reaction were also normal.

CASE 4. J. C., a 43-year-old Negro, entered the hospital with bilateral chronic pulmonary suppuration, apparently not tuberculosis, and a secondary pneumonia. The blood Hinton test was positive, and there was evidence of cardiovascular syphilis with an aneurysm. The control prothrombin time was 25 seconds (22 seconds) and the van den Bergh and bromsulfalein determinations were negative. The patient was started on 4 to 6 gm. of sulfathiazole daily. On the 5th and 9th days of therapy the prothrombin time was 30 seconds (22 seconds). At this time the drug was changed to sulfapyridine, 4 gm. daily. After 5 days the prothrombin time was 30 seconds (23 seconds), the van den Bergh determination showed a trace, and the bromsulfalein retention was 5 per cent. Chemotherapy was discontinued because of no results. Three days later the prothrombin time was 24 seconds (22 seconds).

CASE 5. L. H., a 37-year-old chauffeur, entered with a 5-day history of abdominal pain, anorexia, nausea and vomiting. Examination revealed a mass in the right

lower quadrant of the abdomen, and a diagnosis of a perforated appendix with abscess was made. The appendiceal abscess was drained, and an appendectomy was done. Sulfapyridine was placed in the wound and was given intravenously in a dosage to maintain a blood level between 8 and 9 mg. per 100 cc. The control prothrombin time was 25 seconds (23 seconds), a bromsulfalein test showed 7.5 per cent retention, and the van den Bergh reaction was 2.4 mg. per 100 cc. On the 2nd day of chemotherapy the prothrombin time was 32 seconds (23 seconds); 3.2 mg. of Hykinnone was given. On the 4th day the prothrombin time was 37 seconds (23 seconds), the bromsulfalein retention was 5 per cent, and the van den Bergh reaction was 2.6 mg. per 100 cc. Chemotherapy was discontinued at this time owing to drug fever. The prothrombin time gradually returned to normal, and on the 11th day after the drug was stopped it was 26 seconds (23 seconds) and the van den Bergh determination was 1.7 mg. per 100 cc.

CASE 6. R. H., an 8-year-old Negro, blind since birth, was admitted because of a furuncle of the leg and septicemia. A blood culture yielded a coagulase-positive *Staph. aureus*. The control prothrombin and van den Bergh determinations were normal. The patient was started on sulfathiazole, with a dosage of 6 to 9 gm. daily. He developed a subperiosteal abscess of the tibia, which was drained with ligation of the femoral vein. He then showed evidence of pulmonary miliary tuberculosis. The prothrombin time gradually increased, and on the 15th day of chemotherapy it was 38 seconds (22 seconds) and the van den Bergh reaction was 2.4 mg. per 100 cc. Hykinnone was given at this time, and the prothrombin time returned to normal within 24 hours and remained so until death 4 days later from acute tuberculosis. Shortly before death the van den Bergh was 2.8 mg. per 100 cc. and the bromsulfalein test showed 20 per cent retention.

CASE 7. L. W., a 53-year-old woman, was admitted with a septic prepatellar bursitis, which had developed 2 weeks after a fall. A culture yielded an attenuated microaerophilic beta hemolytic streptococcus (Group A) and a coagulase-positive staphylococcus. The control prothrombin time was 21 seconds (23 seconds), the van den Bergh reaction showed a trace, and the bromsulfalein test was negative. The knee was drained, and the patient was started on sulfanilamide, with a dosage of 4 gm. initially and 6 gm. daily for 8 days, blood levels between 9 and 11 mg. being obtained per 100 cc. On the 6th day of chemotherapy the prothrombin time was 34 seconds (22 seconds), and on the 8th day it was 37 seconds (22 seconds). The van den Bergh and bromsulfalein determinations remained normal throughout. The drug was discontinued because the patient developed a rash, the urine was loaded with sulfanilamide crystals and young red and white cells were present in the blood. Two days later the prothrombin time was 28 seconds (22 seconds); 3 days later it was 24 seconds (22 seconds).

CASE 8. D. W., a 9-year-old girl, was admitted with a diagnosis of osteomyelitis of the knee and staphylococcal bacteremia. She had received chemotherapy prior to admission. The control prothrombin time was 31 seconds (22 seconds), and the van den Bergh reaction was negative. The patient was started on large doses of sulfadiazine, 9 to 11 gm. per day, and the usual supportive treatment. After 5 days the prothrombin time was nor-

ml and showed no further change, in spite of large amounts of sulfadiazine.

CASE 9 W W, a 23 year-old man, was admitted with a diagnosis of acute gonococcal urethritis and a possible arthritis. The control prothrombin time, van den Bergh, and bromsulfalein reactions were all normal. He was started on a dosage of 6 gm of sulfathiazole daily. After 21 days of chemotherapy the prothrombin time was 31 seconds (22 seconds). The drug was omitted, and the prothrombin time returned to normal within 48 hours.

CASE 10 L F, a 46-year-old woman, was admitted with a diagnosis of pelvic inflammatory disease and peritonitis. The control prothrombin, van den Bergh and bromsulfalein tests were all normal. Treatment with sulfapyridine was begun, and later the patient was shifted to sulfathiazole. On the 12th day of chemotherapy the prothrombin time was 31 seconds (22 seconds), on the 14th day it was 34 seconds (22 seconds). The patient became acutely ill, developed thrombophlebitis of the pelvic veins, and was heparinized. Two days after heparin was discontinued, the prothrombin time was 70 seconds (22 seconds) and the van den Bergh reaction was 2.4 mg per 100 cc. Two days later the prothrombin time was 51 seconds (22 seconds), the van den Bergh reaction was 3 mg per 100 cc., and the bromsulfalein test showed 20 per cent retention. The following day the prothrombin time was 32 seconds (22 seconds), the van den Bergh reaction was 2.2 mg per 100 cc., and the bromsulfalein test showed 20 per cent retention. At this time treatment was begun with vitamin K, and 4 days later the prothrombin time was normal, but the bromsulfalein reaction did not return to normal until 1 week later, at which time there was a trace in the van den Bergh reaction.

CASE 11 E L., a 23 year-old man, was admitted for a pneumonectomy for bronchiectasis, at which time sul fanilamide powder was placed in the pleural cavity. The control prothrombin, van den Bergh and bromsulfalein determinations were all normal. The patient was started on 6 gm of sulfapyridine daily. On the 5th day of chemotherapy the prothrombin time was 30 seconds (22 seconds), on the 8th day it was 35 seconds (22 seconds). On the 10th day microscopic hematuria developed and the drug was stopped. Six days later the prothrombin time was 29 seconds (22 seconds). Three days later it returned to normal. The van den Bergh and bromsulfalein determinations remained unchanged throughout.

CASE 12 J C., a 36-year-old man, was admitted for resection of a chondrosarcoma of the sternum, which was complicated postoperatively by pneumonia. The prothrombin time was 25 seconds (23 seconds), and the van den Bergh and bromsulfalein determinations were normal. Sulfapyridine therapy was begun. On the 4th day of chemotherapy the prothrombin time was 33 seconds (22 seconds), the van den Bergh reaction was 1.6 mg per 100 cc., and the bromsulfalein test showed 5 per cent retention. Chemotherapy was stopped at this time. The patient died the following day.

CASE 13 T P., a 39 year-old policeman, entered with a diagnosis of cellulitis of the scalp. The prothrombin time was 24 seconds (22 seconds), the van den Bergh reaction showed a trace and the bromsulfalein retention was normal. Three grams of sulfathiazole was given initially. A culture of the wound yielded an attenuated beta hemolytic streptococcus (Group A) and a coagulase positive staphylococcus. The drug was changed to 8 gm of sul

fanilamide daily, which maintained a blood level between 9 and 12 mg per 100 cc. On the 2nd day of chemotherapy the prothrombin time was 28 seconds (22 seconds), and on the 5th day it was 30 seconds (22 seconds). At this time the dosage was halved. In 2 days the prothrombin time was 26 seconds (22 seconds), the van den Bergh determination showed a trace, and the bromsulfalein test showed 5 per cent retention. Shortly after this the patient developed bilateral deep phlebitis with a positive Homan's sign, which was partially relieved by a paravertebral novocain block. Chemotherapy was omitted, and 3 days later the temperature went to 104°F and the patient developed an acute hemolytic anemia, with a red-cell-count drop to 1,700,000. The prothrombin time was 32 seconds (22 seconds). Three transfusions were given, and the hemolytic crisis lasted only about 24 hours. The prothrombin time returned to normal in 4 days.

CASE 14 J R., a 28 year-old man, was admitted with a carbuncle of the neck, and a *Staph aureus* bacteremia. The temperature was 106°F on admission but the prothrombin time and van den Bergh reaction were normal. The patient was started on sulfadiazine, 9 to 12 gm daily, to maintain a blood level between 15 and 20 mg per 100 cc. The day following admission he developed a thrombophlebitis of the side of the neck and pleuritic chest pain. Accordingly ligation of the external and internal jugular and middle thyroid veins was carried out and the carbuncle was excised. On the 5th day of chemotherapy the prothrombin time was 30 seconds (22 seconds). The patient recovered.

DISCUSSION

Watson and Spink³ did not observe jaundice in any adult receiving less than 3 gm of sulfanilamide per day, and no increase of urinary urobilinogen in these cases. We found no change in prothrombin level in any case receiving 4 gm or less of sulfonamide per day. When daily doses of 4 to 8 gm are given, it is obvious that in a considerable proportion of patients there is a definite decrease in the plasma prothrombin level. Most of these patients were acutely ill and highly toxic, and many had high temperatures. However, fever alone was not accompanied by a decrease in the prothrombin level. Many of our patients were taking little food by mouth and were being sustained with parenteral fluids. Because of the short period of time involved, it is unlikely that inadequate dietary intake was a factor in the decrease of plasma prothrombin. Whether prothrombin deficiency can occur in man solely on the basis of insufficient food intake is still doubtful.¹⁹

The type of infection seemed to make no difference in these cases. It is well known that toxic hepatitis, with jaundice and reduction in plasma prothrombin, may occur in severe infections or in chronic sepsis.^{19, 21} The cause is unknown, although this complication appears to be commoner in cases of peritoneal sepsis. Hence, in these cases both the infection and the chemotherapy exert a hepatotoxic effect. That the infection may play a

considerable accessory role in the depression of liver function is shown by the fact that patients on chemotherapy who had severe infections showed changes in prothrombin levels much more frequently than did those with minor infections.

In the cases reported in the literature only 1 has had serologic evidence of syphilis, and only 1 of ours was similarly affected. Hence this does not appear to be a factor.

In our cases, depression of the plasma-prothrombin level occurred with all four of the drugs used—sulfanilamide, sulfapyridine, sulfathiazole and sulfadiazine. We do not have enough cases to warrant any statistical analysis concerning the relative frequency with which this occurs with the different drugs. However, sulfadiazine was used in only 1 of our cases with an increased prothrombin time, and this was quite mild. In another case, there was a depression of prothrombin level with sulfathiazole, which cleared up on discontinuance of the drug and did not recur later on when sulfadiazine was given.

In most cases, depression in prothrombin level did not occur until the drug had been used for four or five days. In 1 case, however, it occurred forty-eight hours after the drug was begun. In most cases the prothrombin levels returned to normal within a few days after the drug was discontinued. In 1 case, however, a week was necessary.

There is probably an increased incidence of hepatitis in patients with previous liver damage or alcoholism. In 1 of our patients, who had a severely damaged liver, there was a sudden and marked fall in prothrombin level when chemotherapy was begun. However, in most cases, chemotherapy can be continued for some time with little or no effect on the liver. A sulfonamide drug has been given to patients with cirrhosis or jaundice without untoward results.²²

None of our patients developed jaundice and clinical evidence of toxic hepatitis. This may have been due to the fact that the drug was discontinued or used with great caution in those patients who showed changes in the plasma-prothrombin level. In all cases this level returned to normal after stopping of the drug, and there was no evidence of any permanent impairment of liver function. In all cases in which parenteral vitamin K was given, the prothrombin time was normal within twenty-four hours, indicating that the liver was able to respond.

Usually the first sign noted clinically that warns the physician of the occurrence of toxic hepatitis is the appearance of jaundice. By this time it may be too late to prevent a fatality or a major illness superimposed on the patient's infection, even if the drug is promptly stopped. Weir²³ has pointed out

that hepatitis, even to the extent of fatal acute yellow atrophy, can occur without jaundice. Slowly progressive changes in the liver may follow a bout of acute hepatitis in spite of apparent complete recovery, and advanced cirrhosis may follow an old acute hepatitis that never produced any clinical symptoms.²⁴ Since changes in the prothrombin level appear to be an early indication of impending liver damage, the test is of great help in avoiding this major complication.

Although the cause of the hepatitis following sulfonamide therapy is unknown, two possibilities have been considered. It may be another example of drug hypersensitivity, which occurs in an occasional patient owing to idiosyncrasy, or these drugs may regularly produce evidence of hepatic dysfunction. In the case cited by Fitzgibbon and Silver¹¹ and in several others in the literature, there was an interval of several weeks between courses of the drug, and this suggests the former explanation. However, since so many cases show some evidence of liver damage, it is clear that these drugs are inherent liver poisons. A severe hepatitis is probably an accentuation of a usual toxic effect rather than a true drug idiosyncrasy. However, both these factors may play a role in certain cases.

Probably all factors that tend to depress liver function will exaggerate the effects of the sulfonamides in reducing liver function. Hence all possible measures to maintain liver reserve should be taken in patients receiving chemotherapy. It has recently been shown that a high-protein (casein) diet protects rats being given large amounts of sulfanilamide daily.²⁵

CONCLUSIONS

Liver function, as measured by prothrombin, van den Bergh and bromsulfalein tests, was measured in 68 patients receiving sulfonamide therapy for acute infections. Fourteen patients, or 21 per cent, showed a significant decrease in the prothrombin level during chemotherapy. The severity of the infection seemed to be more significant as the cause of prothrombin depression than did the type of sulfonamide used. It is recognized that decreased prothrombin time may be the consequence of factors other than impaired liver function. Inasmuch as serious infection and sulfonamides are both prejudicial to the welfare of the liver, it seems wise to recommend some test of liver function as a routine procedure in this group of patients.

A decrease in plasma prothrombin is found early in impending liver failure. The Quick¹⁸ method of plasma-prothrombin determination is simply and easily performed and is relatively inexpensive. It is suggested that such prothrombin determinations be done every three days in seriously ill pa-

ients receiving sulfonamide therapy. In this way it should be possible to recognize patients in whom serious hepatitis is apt to develop before the symptoms have become clinically alarming.

SIMULTANEOUS HYPERFU AND PARATHY

EDWARD S MILLER, M.D.[†] AND LIE

BOS

THE concurrence of hyperthyroidism and hyperparathyroidism is a clinical rarity; a patient with such a syndrome forms the basis of this report. She presented a confusing symptomatology, so that in retrospect it seems worth while to indicate the clues that could have led to a pre-operative diagnosis. Although such a combination is unusual, this case is by no means an isolated example.

CASE REPORT

M W, a 51 year-old, married housewife, was admitted to the Medical Service of the Peter Bent Brigham Hospital on November 4, 1941. She complained of weakness, abdominal distress and vomiting of 8 months' duration. The past history was of interest in that 10 years previously her physician had noted that her thyroid gland was enlarged. Four years previously she passed what was thought to be a renal calculus. She had no other urinary symptoms. One year prior to admission there occurred a 3-week episode of vomiting and abdominal pain, diagnosed as gall-bladder disease. From 16 months until 2 months before admission the patient took 1 tablet of thyroid each day. The basal metabolic rate was not determined. The

*From the Medical Service, Peter Bent Brigham Hospital.

†Formerly, medical house officer, Peter Bent Brigham Hospital.

The hemoglobin was 10.1 gm., and the blood smear was normal except for moderate variation in the size and shape of the red cells. Urinalysis was negative. The serum cholesterol was 181 mg. per 100 cc. The gastric contents contained free acid after histamine. The basal metabolic rates in a series of determinations were +36, +29, +23, +25 and +31 per cent. The decholin circulation time was 12 seconds. The heart and lungs were negative to x-ray examination, although the trachea was displaced to the left. The bony thorax was normal. A gastrointestinal series demonstrated no abnormalities. Prostigmine injection produced no change in muscular activity.

During the patient's stay on the Medical Service her temperature fluctuated each day, rising as high as 101°F. by rectum. The heart rate was usually between 120 and 150, even during sleep. She was hyperactive and retched frequently. She had been taking iodine during the month prior to admission, and this drug was continued. Myasthenia remained a prominent aspect of the symptomatology. There was no clinical improvement, and on November 17 the patient was transferred to the Surgical Service for thyroidectomy.

The following day operation was performed under novocain anesthesia. A rather large, vascular, hyperplastic thyroid gland was found, and a radical subtotal thyroidectomy was performed. In addition, there was a yellowish tumor at the lower pole of the left lobe, which had the gross appearance of a parathyroid gland. Venous blood was taken for chemical determinations, and the tumor was removed.

Significant blood studies were as follows:

TIME	CALCIUM mg./100 cc.	PHOSPHORUS mg./100 cc.	PHOSPHATASE Bod. units/100 cc.
At operation .	17.2	2.5	3.2
Postoperative day:			
2nd . . .	16.4	3.1	
4th . . .	11.4	1.0	
6th . . .	11.4		
9th . .		2.4	
14th .	7.6	2.2	
Normal	9-11	2.5-4.5	2-4

It is evident that during and immediately after operation this patient's serum calcium was considerably elevated whereas the phosphorus was decreased—findings that are typical of hyperparathyroidism. The normal phosphatase level was consistent with the paucity of bone changes.

The postoperative course was uneventful except for the development of mild tetany on the 7th day, controlled with calcium gluconate intravenously. Other x-ray studies at this time demonstrated a nonfunctioning gall bladder. Films of the long bones showed the bone detail and calcium content to be normal except for slight osteoporosis of the femurs. Skull films revealed a normal sella, with a mild degree of osteoporosis of the vault. Intravenous urograms were normal. Moderate hypochromic anemia persisted. Three weeks after operation the basal metabolic rate was -26 per cent. The patient returned home on a maintenance dose of viosterol and calcium gluconate.

The patient was seen again 4 months after operation, at which time she was in excellent health and had regained the 40 pounds previously lost. The only complaints were soreness of the shins and ankle edema, which appeared only with walking. These phenomena were attributed to the prolonged period of confinement to bed. The basal metabolic rate was -1 per cent, the serum calcium 10.2 mg. per 100 cc., the serum phosphorus 3.1 mg., the

phosphatase 1.1 Bodansky units, and the hemoglobin 14.9 gm.

Pathological report: The thyroid tissue when removed weighed 53 gm., was homogeneously pink, and showed a few small nodular areas. Histologic sections revealed closely spaced follicles, some of which were lined with low cuboidal cells and others with tall columnar cells (Fig. 1). The stroma was richly vascularized, and there were occasional collections of lymphoid tissue. The findings were typical of hyperplasia of the thyroid gland with iodine involution.

At the left lower pole of the thyroid gland was a parathyroid gland weighing 2.5 gm. Microscopic examination disclosed closely packed cells in cords, with occasional alveolar formations. The cells were polyhedral and small, and contained finely granular and slightly basophilic cytoplasm with round nuclei rich in chromatin (Fig. 2). Some of the alveolar formations were lined with these cells and contained small amounts of pinkish material. There were numerous eosinophils in the highly vascular stroma. The pathological diagnosis was adenoma of the parathyroid gland.¹

CASES IN THE LITERATURE

We were able to find in the literature 5 cases of this combination of hyperthyroidism and hyperparathyroidism. Meyer-Borstel's² patient had severe Graves's disease associated with generalized osteitis fibrosa cystica. This patient was seen in 1922, at a period when the association between the bone disease and hyperparathyroidism was not clearly defined. Consequently, when she underwent thyroidectomy a parathyroid tumor was neither searched for nor found. Ballin and Morse³ cited a case with symptoms of hyperthyroidism in which "a calcified adenomatous goiter" was removed. During the next few years the patient developed bone pains and decalcification, and this time a parathyroid adenoma was found at operation. Ball⁴ reported a case with an elevated basal metabolic rate and an increased serum calcium, in which the combined diagnosis was made clinically. At operation a "colloid and fetal adenoma" of the thyroid was found. Search for a parathyroid tumor was fruitless. The serum calcium remained elevated after operation. Hellström's patient⁵ had a basal metabolic rate of +50 per cent, a serum calcium of 14 mg. per 100 cc. and generalized osteitis fibrosa cystica. She was not subjected to operation. Noble and Borg⁶ reported a case that was confirmed at operation. Cooley's patient⁷ probably does not fall into this group, for although the basal metabolic rate was +23 per cent, there was a colloid goiter histologically.

DISCUSSION

Our patient's preoperative course was unusual in several respects, and was the subject of considerable discussion. She had taken a daily dose of thyroid for an extended period of time, but this

medication was stopped two months before entry. It was believed that her symptoms of thyrotoxicosis in this patient. Another confusing symptom was abdominal distress and tenderness. These prob-

FIGURE 1. Photograph of Section of Thyroid Gland, Showing Hyperplasia with Iodine Involution (eosin and methylene blue, 200 \times).

could not be attributed to this. There was a considerable degree of nausea, vomiting, weakness and lems were of course clarified by the finding of a parathyroid adenoma

FIGURE 2. Photograph of Section of Parathyroid Adenoma (eosin and methylene blue, 200 \times).

anemia. These symptoms can occur in hyperthyroidism, but they are not commonly so severe as In Table 1 are listed the most frequent symptoms and signs characteristic of hyperfunction of the

thyroid and parathyroid glands, as well as those common to both.⁸⁻¹¹ It is evident from this table

TABLE 1. *Symptoms and Signs in Hyperfunction of the Thyroid and Parathyroid Glands.*

SYMPTOM OR SIGN	PRESENT IN CASE REPORTED
Common to hyperthyroidism and hyperparathyroidism:	
Mass in neck	+
Weight loss	+
Anorexia	+
Nausea and vomiting	+
Weakness and fatigue	+
Osteoporosis	+
Polyuria and polydipsia	+
Increased urine calcium	+
Increased serum phosphatase	+
Found particularly in hyperthyroidism	
Nervousness	+
Tremor	+
Tachycardia and palpitation	+
Eye signs	+
Thrill and bruit over gland	+
Perspiration and warmth	+
Pressure symptoms (cough and dyspnea)	+
Diarrhea	+
Oligomenorrhea or amenorrhea	+
Increased basal metabolic rate	+
Good appetite	+
Found particularly in hyperparathyroidism.	
Metastatic calcification, especially renal stones	+
Abdominal distress and pain	+
Cold extremities	+
Hypochromic anemia	+
Increased serum calcium and decreased serum phosphorus	+
Osteitis fibrosa cystica, bone pains, bone tumors, fractures and deformities	+
Renal insufficiency	+
Bradycardia	+
Constipation	+

that there are striking and confusing clinical similarities. In the presence of thyrotoxicosis there are relatively few factors that lead one to suspect a superimposed hyperparathyroidism. These include

osteitis fibrosa cystica, metastatic calcification, marked hypochromic anemia and, of course, increased serum calcium. In the case under discussion, the significant clinical features that could have led to the proper diagnosis were a history of renal stone, abdominal distress, anemia, marked nausea and vomiting, and unusual asthenia.

One may speculate on a possible common etiologic factor in this syndrome. The obvious link that comes to mind is the pituitary gland. In this patient, however, there was no evidence of pituitary disease.

SUMMARY

A case of simultaneous hyperthyroidism and hyperparathyroidism is presented. Other case reports are reviewed.

The salient factors in diagnosis are summarized.

COMPLETE SITUS INVERSUS

Report of a Case with Calcareous Aortic Stenosis and Cor Bovinum

JOSEPH G. PASTERNAK, PASSED ASSISTANT SURGEON, U.S.P.H.S.*

STATEN ISLAND, NEW YORK

ALTHOUGH congenital cardiac anomalies and defects have frequently been found associated with situs inversus,¹ reports of acquired cardiac lesions are rare. Owen² reported a case of mitral stenosis, and King³ one of syphilitic aortitis, aortic insufficiency, cardiac hypertrophy and myocarditis with a mural thrombus.

heart. There was no history of rheumatic fever. An electrocardiogram was interpreted as showing dextrocardia. There was complete inversion of Lead I and transposition of Leads 2 and 3. The heart was compensated, only moderately enlarged, and showed no evidence of myocardial damage. From the age of 15, the patient had worked at laborious occupations, unrestrained. He stated that he had had a serious lung or heart ailment in 1907.

FIGURE 1 *Situs Inversus Totalis*
Note the greatly hypertrophied heart

The first case of complete situs inversus with calcareous aortic stenosis, cor bovinum and multiple pulmonary infarcts, is now reported.

CASE REPORT

A 43-year-old Swede entered the United States Marine Hospital on September 15, 1941, because of a cold and productive cough of 3 weeks duration. He had been treated in this hospital for gonorrheal urethritis in 1938. At that time a diagnosis of dextrocardia with aortic stenosis was made. The patient had no symptoms referable to the

heart. On admission he complained of shortness of breath on exertion, paroxysmal nocturnal dyspnea and swelling of the ankles. He had persistent dull pain in the right chest and a feeling of rawness behind the lower sternum.

On physical examination the patient was found to be in moderate distress in congestive heart failure and cyanotic. There was marked edema of the lower extremities. The pulse was 96, regular, small in volume and equal on both sides. The apex beat was in the right 6th inter-space at the anterior axillary line. There was a marked systolic thrill in the 2nd and 3rd intercostal spaces to the left of the sternum. In this area a loud, harsh systolic murmur was heard which was audible over the entire precordium and in the neck. The aortic second sound

*Director, Department of Pathology, United States Marine Hospital, Staten Island, New York.

was replaced by a short, faint diastolic murmur. The liver was palpably enlarged on the left side.

An electrocardiogram showed inversion of the P and QRS waves in Lead I and marked right-axis deviation. The T waves were upright in all leads. Comparison of this electrocardiogram with the one made 3 years previously disclosed evidence of left-ventricular strain in the new one. A roentgenogram of the chest gave the maximum heart measurements as 10.8 cm. to the right and 7 cm. to the left; the transverse diameter of the chest was 28.4 cm. A lateral view showed shadows suggestive of aortic calcification. Roentgenograms after a barium

scopic examination revealed scattered areas of interstitial fibrosis and foci of old myocardial scarring. The coronary arteries showed more or less diffuse fibrosis of their walls with occasional foci of atheroma and calcification in the intima. Multiple old and recent infarcts were present in all lobes of both lungs.

SUMMARY

Complete situs inversus associated with calcareous aortic stenosis, cor bovinum and multiple pulmonary infarcts is reported for the first time.

FIGURE 2. *Calcareous Lesion of the Aortic Valve.*

meal showed complete transposition of the gastrointestinal tract. The Wassermann and Kahn tests were negative.

The patient responded to treatment for 6 weeks and thereafter went downward. He died December 20.

Autopsy. There was complete situs inversus (Fig. 1). The heart weighed 810 gm. The aortic orifice was stenosed and deformed, and the cusps were fused and massively calcified (Fig. 2). The calcified ring measured 4 mm. in thickness. Microscopic examination showed the calcified cusps to consist of hyalinized scar tissue with more or less cartilaginous metaplasia and calcification. The myocardium was markedly hypertrophied. Micro-

The cardiac lesions were compatible with an old rheumatic infection.

I am indebted to Drs. G. A. Abbott and Henry I. Russek for the clinical data used in this report.

MEDICAL PROGRESS

PATHOLOGY: DISEASES OF BONE

TRACY B MALLORY, MD *

BOSTON

TO MOST physicians the rarer diseases of bone with their multiple polysyllabic and still more confusing eponymic terminologies constitute the most perplexing field in medicine, a field so esoteric that it is apt to be relegated far back into the realms of the subconscious. This confusion, it must be admitted, is not unwarranted since there is justifiable suspicion that it afflicts the experts to an almost equal, albeit unadmitted, degree. In the last few years enough new observations have been placed on record to help in delineating these various entities to make a summary worth while at the present time.

HAND-SCHULLER-CHRISTIAN'S DISEASE, LETTERER-SIWE'S DISEASE AND EOSINOPHILIC GRANULOMA OF BONE

Hand-^{1 2} Schuller-^{3 4} Christian's⁵ disease, in its fully developed form as first described by Christian with the triad of multiple defects of cranial bones, exophthalmos and diabetes insipidus, has become a familiar picture, in the textbooks at least, though probably relatively few physicians have actually had a case under their own observation. That other cases lacking one or more features of the triad exist is less well known, and such cases are more likely to escape recognition and report. Yet Burger,⁶ in an assemblage of cases from the literature, found that 22 of 48 cases fell in this category. Also less generally realized is the possibility of other osseous localizations, in the pelvis, ribs, phalanges and even the long tubular bones, of lymph node and splenic involvement and, still more important, since they are life-endangering, of destructive lesions of the brain itself (Letterer⁷).

For somewhat over a decade, since the comprehensive studies of Rowland,⁸ Hand-Schuller-Christian's disease has been classified with the disturbances of lipid metabolism — Gaucher's disease with its storage of keratin, Niemann-Pick's disease with phosphatide abnormality and Hand-Schuller-Christian's disease as the corresponding disturbance of cholesterol metabolism. Significant reasons for questioning the correctness of this con-

venient schematization exist and have recently been re-emphasized (Letterer, Wallgren⁹ and Farber^{10 11}).

From the pathological point of view it is evident that Hand-Schuller-Christian's disease is not a simple so called "storage disease," like Niemann-Pick's or Gaucher's disease. It invariably shows the histological characteristics of a granulomatous process accompanied by significant grades of inflammatory reaction, both leukocytic and fibrous. Yet cholesterol storage, which can readily be provoked by the feeding of cholesterol to rabbits, does not result in a granulomatous inflammatory reaction. Moreover, the spontaneous familial disease of man characterized by cutaneous xanthelasma, hypercholesteremia and extensive deposits of cholesterol and its esters in tendon sheaths and other tissues — familial xanthomatosis^{12 13} — is not associated with granulomatous reactions and never shows the destructive lesions of bone that characterize Hand-Schuller-Christian's disease. It is also noteworthy that no familial or even racial tendency has ever been noted in the latter, in contrast to the other storage diseases.

Cases of Hand-Schuller-Christian's disease do not ordinarily come to the attention of a physician in the early stages of their development. The bone lesions are usually so slow in their development and so painless that they remain unnoticed for a long period. When, however, the disease has been recognized at a comparatively early period or a fresh lesion is biopsied in a case of longer standing, it has been the usual experience that the granulomatous reaction is present but there is as yet little or no lipid deposit (Freund and Rippes¹⁴). Cholesterinization occurs only with progression of the disease and is secondary, not primary (Letterer⁷).

As the significance of cholesterol has diminished in the conception of the pathogenesis of Hand-Schuller-Christian's disease, more attention has been devoted to the antecedent granulomatous reaction and new relations have become apparent. Wallgren,⁹ for instance, in an extremely lucid article argues that Letterer-Siwe's¹⁵ disease or leukemic reticulosis (Letterer¹⁶), or diffuse reticuloendotheliosis (Siwe¹⁷), or nonlipoid histiocytosis (Foot and Olcott¹⁸) is only a variant of the same pathologic process. Typical Letterer-Siwe's dis-

*Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress, Annals of Vol. III, 1942* (Springfield, Ill. no. 3, Charles C. Thomas Company, 1942, \$5.00).

*Assistant professor of pathology, Harvard Medical School, director, Department of Pathology and Bacteriology, Massachusetts General Hospital.

ease rarely occurs beyond two years of age and runs a rapidly and, it is at present believed, inevitably fatal course. It is characterized clinically by fever, skin rash, rapidly progressive anemia and purpura and histologically by marked proliferation of the so-called "reticuloendothelial" (monocytic and clasmotocytic) cells in many parts of the body, particularly the skin, the lymph nodes and the spleen. Occasionally the process simulates neoplasm so that it has been classified with the pseudo-leukemias; more often it presents an inflammatory, granulomatous character that suggests infection. Some of these cases show significant amounts of lipid storage in the proliferating cells. Certain cases, moreover, otherwise typical of Letterer-Siwe's disease, have shown focal destructive lesions of bone, with or without lipid deposits, quite indistinguishable from Hand-Schüller-Christian's disease (Schultz, Wermbter and Puhl¹⁹ and Wallgren [Case 2]⁹). If the series of reported cases are listed in the order of their chronicity, as Wallgren has done, every grade of transition between the two diseases can be seen. In early infancy a malignant course is invariable, and the patient dies before complete development of the lesion, and before time has elapsed sufficient for secondary lipid degeneration. In later infancy greater chronicity is the rule and some of the features of Hand-Schüller-Christian's disease begin to make their appearance. From the age of two onward the disease is ordinarily chronic, lipoidal stages develop with considerable frequency, and by the age of three or four the typical picture of Hand-Schüller-Christian's disease is the rule.

A third condition, independently described as a new disease entity by Otani and Ehrlich²⁰ and by Lichtenstein and Jaffe²¹ as solitary or eosinophilic granuloma of bone, may well, in the opinion of Farber,^{10, 11} be still another variant of the same pathologic entity. The cases described by these two pairs of authors occurred for the most part in children in the later stages of childhood but also in adults, and were characterized by tumorlike destructive swellings of bone, usually single but occasionally multiple. Not infrequently the patients showed low-grade fever and leukocytosis, and occasionally blood smears disclosed significant grades of eosinophilia. Either excision of the lesion or x-ray treatment following biopsy was followed by rapid cure. Histologically the process is a granulomatous inflammatory lesion with marked accumulation of mononuclear phagocytes, often many foreign-body giant cells and variable numbers of eosinophils, sometimes tremendous. In one of Otani and Ehrlich's cases, however, eosinophils were entirely absent. It is interesting to note that the same histological picture was well described in a

beautifully illustrated paper by Fraser²² in 1935 as a variant of Hand-Schüller-Christian's disease.

Farber¹¹ has collected a group of 10 cases of granulomatous destructive lesions of bone. In this material he was able to find every grade of transition from typical Hand-Schüller-Christian's disease to the eosinophilic granuloma of Otani and Ehrlich and of Lichtenstein and Jaffe. Clinically typical Hand-Schüller-Christian's disease may show in various lesions xanthomatoid pictures with or without eosinophils, and eosinophilic granulomas without lipid degeneration. My own experience with 5 cases, only 2 of which have yet been published,^{23, 24} is entirely in accord with these findings. Among these cases was an example of clinically typical Hand-Schüller-Christian's disease in a child, in which a lymph-node biopsy yielded the typical picture of eosinophilic granuloma without lipid deposits; also there were 2 cases in adults with solitary lesions of the cranial bones, one with and one without eosinophils, but both showing extensive cholesterol deposits and the characteristic histologic picture of Hand-Schüller-Christian's disease.

One final variation in the picture remains to be mentioned. Farber points out that in certain cases in children the eosinophil proliferation may be so rapid that differentiation is incomplete and eosinophilic myelocytes may dominate the histologic reaction. The possibility of confusion with neoplastic processes of the myeloid series of cells is very great, and beyond question certain of these lesions have been classified as myelomas and myeloblastomas by competent observers.

Strongly suggestive evidence therefore lies at hand that all these various syndromes represent a single disease entity—rapidly fatal in the infantile forms, which have been described as Letterer-Siwe's disease and reticuloendotheliosis; chronic, but still of serious import because of the likelihood of cerebral and hypophyseal involvement, in early childhood (Hand-Schüller-Christian's disease); and comparatively benign in later childhood or in the adult, where the usual picture is that of eosinophilic granuloma. Proof of this identity must of course await the discovery of the etiology. Recent pathological studies point strongly away from a fundamental metabolic disorder and in the direction of a specific infectious agent.

OSTEITIS FIBROSA DISSEMINATA, POLYOSTOTIC FIBROUS DYSPLASIA, REGIONAL FIBROCYSTIC DISEASE AND ALBRIGHT'S DISEASE

Under the terms listed in the above heading and more than a score of other names, examples have been recorded of a confusing group of skeletal lesions for some of which fairly clear clinical and

pathologic pictures are beginning to emerge. The most extensive skeletal changes are usually found as part of a syndrome that includes changes in the skin and in the function of certain endocrine glands. The syndrome has been most clearly described by Albright and his numerous collaborators,^{25, 26} although individual case reports have been found dating back at least to von Recklinghausen. The essential features are as follows: multiple destructive lesions of bone simulating closely the generalized osteitis fibrosa of hyperparathyroidism and renal rickets but showing a distinct tendency to unilateral distribution; pigmented spots in the skin, also often restricted to one side of the body; and precocious puberty in female but not in male patients. An unusual feature of the precocious puberty associated with this syndrome, sharply separating it from other forms such as may occur with adrenal or ovarian tumors, is that there is no loss of fertility. Indeed one patient with this disease, a Peruvian girl, Lena Medina, won world-wide notoriety when she was delivered of a child at the age of five.²⁷

It is clear that the bone lesions are not due to abnormal parathyroid activity. Although the blood calcium and phosphatase may be moderately elevated in the active stages of the disease, the phosphorus is never depressed and there is no increased excretion of calcium in the urine. The uninvolved bones fail to show the generalized decalcification characteristic of hyperparathyroidism. Finally, under mistaken diagnosis, the parathyroid glands have several times been explored and on one occasion the removal of two normal glands was followed by unmistakable symptoms of tetany.²⁸

As in Hand-Schüller-Christian's disease, however, there is reason to doubt that all cases, or even, in the opinion of Lichtenstein and Jaffe,²⁹ any considerable proportion of them, present the complete triad of bone lesions, skin pigmentation and precocious puberty. Female patients with typical bone and skin lesions may not give a history of precocious puberty. Characteristic multiple bone lesions of unilateral distribution are found without skin pigmentation or endocrinopathy. Monomelic involvement—the restriction of lesions to the bones of a single extremity—has frequently been observed. Finally, single lesions of bone—so-called "osteitis fibrosa localisata"—are comparatively common which by x-ray and on gross and histologic examination of excised specimens are indistinguishable from individual lesions of the disseminate type.

From the clinical point of view, certain similarities between the localized and disseminate forms are apparent. The lesions usually appear in youth, commonly in later childhood or adolescence. Their development is evidently slow and often associated

with little pain. Consequently they may remain undiscovered for long periods of time until a pathologic fracture and consequent x-ray examination call attention to their presence. After a certain period they tend to become quiescent, although it is doubtful if they ever spontaneously heal and disappear. Little evidence exists, however, that the localized disease ever tends to become generalized. Both flat and tubular bones may be involved, and in the latter the epiphysis is almost always spared. Although the metaphysis is most frequently involved, even the midportion of the diaphysis may be the site of a lesion.

From the roentgenologic point of view the lesions closely simulate those of hyperparathyroidism, with the notable exception that the uninvolved bones are completely normal without evidence of generalized decalcification.^{27, 30} The process appears primarily destructive and usually expansile, with marked thinning of the cortex and no periosteal reaction unless complicated by fracture. Usually the density of the bone is considerably, though often irregularly, diminished and the picture frequently suggests cyst formation, an impression belied by the pathologic findings, which rarely show cyst formation of more than microscopic dimensions in the midst of solid tissue.

When one of these lesions is explored it is found to consist of fibrous tissue of variable density, which usually feels gritty. Microscopic examination proves this to be due to spicules of poorly formed and often imperfectly calcified membranous bone which, in the opinion of Lichtenstein,³¹ is formed by metaplasia from the fibrous tissue. In some cases islands of hyaline cartilage are present.

In the opinion of Lichtenstein and Jaffe²⁹ this histologic picture is sufficiently distinctive to be regarded as specific, even pathognomonic. If they are correct, another not uncommon condition must be brought into the fold. This is the tumor, or at least tumorlike condition, of the jaws that has been variously reported as ossifying fibroma and fibrous osteoma.³¹⁻³⁴ As Lichtenstein³¹ has pointed out, the histologic picture is identical with that of fibrous dysplasia. As in the latter disease the onset is in youth, usually in adolescence, and the outlook is favorable.

The majority of observers are as yet unprepared to accept the opinion of Lichtenstein and Jaffe that the histologic picture is pathognomonic, and point out that osteitis fibrosa is seen in hyperparathyroidism, in renal rickets, in some stages of Paget's disease and perhaps even in certain infectious lesions of bone. Lichtenstein and Jaffe, in contrast, assert that in most cases with a biopsy of adequate dimensions there are sufficient differences in the character of the bone formation and bone destruction as well as in the fibrous tissue substrate to

make distinction readily possible. The wealth of material provided by the clinic of the Hospital for Bone and Joint Diseases is so great, and the authors have evidently studied it with such thoroughness and care, that their opinions deserve the most serious consideration.

In another direction also the specificity of the lesion they have described has been challenged. This is shown by the frequent use of the term "fibrocystic disease,"³⁵ under which solid and cystic lesions have been indiscriminately grouped. Jaffe and Lichtenstein,³⁶ again, have given special consideration to cystic disease of the bone. Under the name of "solid unicameral bone cyst" they describe their experience with 19 cases of true bone cyst. These are solitary, fluid-filled lesions of long tubular bones, most often of the humerus and femur. The surrounding cortex is expanded and thinned. The lining is ordinary fibrous tissue. They arise in youth, particularly in adolescence. The process starts in apposition with an epiphyseal line, but if untreated may extend to involve the major portion of the shaft. With growth, normal bone may be laid down between the cyst and the epiphyseal line so that the lesions may appear to migrate toward the center of the shaft.

Whatever the ultimate verdict may be regarding the specificity of fibrous dysplasia and the relation of the localized and disseminate forms, this group of lesions well warrants increased attention from clinician and pathologist alike. The former should be on his guard to pick up the localized form of the disease in any patient with a history of repeated fractures, particularly those of the same bone. He must likewise guard by careful blood-chemical determinations against confusing the generalized disease with hyperparathyroidism and subjecting his patient to a needless cervical operation. For the pathologist the greatest danger in this group of lesions lies in the possibility of confusion with malignant neoplasms, particularly in cases complicated by fracture and atypical reparative processes. The development of sarcoma in such a lesion has yet to be reported. Extreme caution should be observed in the face of scanty and possibly inadequate biopsies, and the precaution of checking with expert radiologic opinion should never be omitted.

In the realm of therapy little new has been offered. Nothing whatever is known that will affect the progress of the disseminate disease. Individual lesions in important bones may be treated by curettage, packing with bone chips or the use of solid bone grafts. Recurrence, however, is not infrequent. Radiation therapy is entirely ineffective.

The etiology of this entire group of lesions remains completely mysterious. Their localized character and the well-marked tendency to uni-

lateral distribution rule out a hormonal basis, except, perhaps, as a contributing factor. A congenital abnormality of bone development, possibly mediated in some way through the nervous system, seems the best solution as yet offered. Bremer³⁷ has suggested an interesting hypothesis based on analogy with the development of the air sac in the humerus of chickens. This has been shown to be dependent on the action of estrin, and the bone is hollowed out immediately below the epiphyseal line by an osteoclastic osteitis fibrosa very similar to the lesion of hyperparathyroidism. The development of lesions during adolescence and their association in certain cases with precocious puberty would fit such a theory. Although of great interest, it is manifest that any such hormonal influence could explain only a part of the picture.

OSTEOID OSTEOMA

Under this title Jaffe^{38, 39} and Lichtenstein⁴⁰ have described what appears to be a new disease entity probably clinically misinterpreted heretofore as sclerosing, nonsuppurative osteomyelitis or cortical bone abscess. The lesion proper consists of a rather small spherical nodule of vascular mesenchymal tissue closely packed with osteoblasts, which quickly lay down intercellular osteoid tissue that is slow to calcify. Eventually, however, calcification and even hypercalcification beyond the density of normal cortical bone occur. Equally characteristic of the process is the stimulation of reactive proliferation in the surrounding bone, so that the small primary focus is more or less encapsulated by a comparatively large mass of newly formed and very dense cortical bone. The lesion has been seen in nearly all the bones of the extremities and also in the vertebrae, but has not as yet been observed in the skull, pelvis or ribs. It develops in youth, commonly between the ages of ten and twenty-five, and appears to be more frequent in males than in females. Almost invariably, the principal symptom is pain, which is extremely persistent but generally not of great intensity, since several months commonly elapse before the patient comes under surgical observation. Local examination usually reveals tenderness and slight swelling. There are no systemic evidences of infection, such as fever and leukocytosis, and there is seldom any convincing history of trauma.

The roentgenographic picture constitutes the most valuable single diagnostic guide but is frequently misinterpreted. In the early stages of the disease the osteoid osteoma proper is indicated by a round or oval focus, 0.5 to 1.0 cm. in diameter, of relative radiolucency. This is surrounded by a perifocal reaction of newly formed and very dense bone, which may be limited to a relatively

narrow ring or may spread for several centimeters about the lesion. Later in its evolution, when the osteoid osteoma tends to become calcified, it no longer appears as an area of uniform rarefaction but begins to show focal and later complete opacity. This is the stage at which it is very apt to be misinterpreted as a sequestrum. To bring out the details of the lesion overexposed plates are frequently necessary.

Treatment in all the cases yet reported has consisted in excision of the osteoid focus and of the overlying reactive bone. This has been followed by immediate relief of pain, and no recurrences are on record.

The etiology remains mysterious. Infection seems to be ruled out by the absence of systemic reaction, by the complete absence of histologic evidence of inflammation in the lesion itself and by the negative results of all bacteriologic investigations. The pathologic picture in no way resembles that of aseptic necrosis of bone, and there is rarely a convincing history of trauma. Jaffe^{38, 39} strongly supports a neoplastic origin. Against this must be cited the limited growth capacity of the primary osteoid focus, which regardless of duration rarely exceeds 1.5 cm. in diameter.

CAISSON DISEASE OF BONE

Aseptic necrosis of bone of infarctlike character without demonstrable cause for vascular occlusion has long been recognized as the anatomic basis of Legg-Perthes's, Osgood-Schlatter's, Kocher's and Kienböck's diseases. Kahlstrom, Burton and Phemister⁴¹ have recently reported 4 cases of extensive aseptic necrosis, involving numerous bones, in victims of caisson disease. The lesions are limited to the long tubular bones of the extremities. When the lesions were situated in the epiphyses and bordered on joints, collapse of weight-bearing portions usually occurred, overlying articular cartilage broke down, osteocartilaginous loose bodies often appeared, and extensive arthritis deformans developed. When the necrotic bone focus was not in approximation with a joint surface, collapse did not occur and attempts at organization were apparent, but only in the smaller foci was this ever complete. In the larger areas the necrotic focus persisted indefinitely (up to thirty-five years in one case) with only a narrow shell of densely calcified reactive bone at its periphery. The pathogenesis is discussed by these authors, and two alternative theories are contrasted. The first is intravascular air embolism. Against this was the absence in one autopsied case of any infarcts of internal organs despite multiple foci in the bones. Secondly, the attempt to reproduce the picture in animals by air embolism was unsuccessful. The alternative concept is the extravascular liberation of gas

bubbles in such numbers that circulation is arrested by extravascular tension. In favor of this theory is the restriction of lesions to the tubular bones, which contain fatty rather than hematopoietic marrow. It has been shown that fat tissue absorbs four to five times as much nitrogen under conditions of increased pressure as do other kinds of tissue. Therefore far more gas is available for release, and its sudden liberation within a non-expandable bony shell may adequately explain the development of the lesion.

It should be pointed out, however, that indistinguishable multiple lesions of bone have been observed by Chandler⁴² and more recently by Kahlstrom, Burton and Phemister⁴³ in patients who have never been exposed to high atmospheric pressures. The general pathogenesis of aseptic necrosis of bone therefore remains as heretofore an unsolved problem.

MELORRHEOSTOSIS

This formidable name is derived from two Greek words meaning "limb" and "I flow." It refers to the extraordinary appearance of affected bones on x-ray examination. This was originally described by Léri and Joanny⁴⁴ as *coulée de bougie*, because of its resemblance to the incrustations of molten wax along the side of a candle. Franklin and Matheson⁴⁵ have reported another case and reviewed the literature, which now includes 39 cases.

The affected bones are markedly thickened by irregular cortical overgrowths which project chiefly outward, although some encroachment on the marrow cavity may also occur. Usually multiple bones of a single extremity are involved and there is no greater frequency in the upper than in the lower limbs. Bilateral involvement has been observed in 5 cases, whereas the case of Franklin and Matheson showed almost perfect unilateral distribution, including the parietal and mandibular bones, the innominate bone and two ribs, as well as the tubular bones of the extremities, a more frequent site. Nine vertebrae likewise showed changes limited to the right side of the neural arch, but a single vertebra, the fifth lumbar, showed bilateral involvement. Histologic examination showed distortion and compression of the bone pattern with increased osseous density and a proportionate decrease in the number and size of the Haversian canals. There was evident predominance of bone formation over destruction, and although rare osteoblasts were identified, no osteoclasts were seen. The marrow was usually fibrous.

The symptoms of this unusual disease are vague and may be little more than the discomfort of the greatly increased weight of an affected limb. On examination, asymmetry of the face or limbs is usually apparent and nodular bony thickening may

be felt. The x-ray appearance of the *coulée de bougie* is pathognomonic.

ALBERS-SCHÖNBERG DISEASE, MARBLE BONES OR OSTEOPETROSIS

In this disease, which usually makes itself apparent in early childhood, the bones are of unusual density as judged by x-ray examination but of abnormal fragility from the clinical point of view, since they are prone to sustain repeated fractures from mild trauma. The underlying defect appears to be an inability to resorb bone, so that when new bone is laid down during growth the old bone is not removed. This may lead to pinching of nerves at their points of exit from the skull, and van Creveld and Heybroek⁴⁶ report blindness due to optic atrophy as the first symptom in a child. When the normal bone markings are not completely obliterated it is not unusual to see in x-ray films of the extremities transverse lines of increased density, which parallel the epiphyseal line. These are similar to the lines that can be produced experimentally by the intermittent feeding of phosphorus. Van Creveld and Heybroek made the interesting observation that these lines were laid down seasonally, the maximal density occurring in the autumn. With the failure of bone resorption, medullary cavities may fail to develop normally, leading to a myelophthitic anemia. The spleen and liver may be enlarged by compensatory myelopoiesis, and primitive cells of both the erythroid and myeloid series may be found in the peripheral blood. In certain cases the hematologic abnormalities completely dominate the clinical picture.

Metabolic studies in the hands of Kramer, Yuska and Steiner⁴⁷ showed normal levels in the blood for calcium, magnesium, phosphorus and phosphate. Chemical examination of the bone showed hypermineralization and an increase in the carbonate content. Further studies are, however, desirable since their case was complicated by moderately severe rickets.

The etiology of the disease is completely mysterious. The condition is evidently congenital and has been noted at birth. Drukker⁴⁸ in a survey of 121 cases found a familial incidence in 40 per cent.

CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITALANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

CASE 28511

PRESENTATION OF CASE

First admission. A sixty-five-year-old physician was admitted because of a sense of oppression in the chest and "wheezing" at night.

Fourteen years prior to admission he was accidentally found to have a blood pressure of 200 systolic, 130 diastolic, and auricular premature beats. Accordingly he gave up smoking and took potassium sulfocyanate, $1\frac{1}{2}$ gr. three times a day every other month. Two years later the blood pressure was 190 systolic, 100 diastolic.

Eleven years previously, after working particularly hard, he noted a slight amount of dizziness, occasional episodes of ringing in the ears and subcutaneous hemorrhage of the left arm. Physical examination revealed subconjunctival hemorrhage of the left eye. The heart was enlarged, the apex being 10 cm. to the left of the midsternal line in the fifth intercostal space. The heart sounds were of good quality, and a harsh systolic murmur was audible at the apex and in the aortic area; no diastolic murmurs were heard. The pulse was irregular, owing to the presence of many premature beats, and the blood pressure was found to be 195 systolic, 115 diastolic. Fluoroscopic examination revealed a slight amount of cardiac enlargement and a marked tortuosity of the aorta, with a prominent knob. The patient was advised to limit his activities further, and to continue the potassium sulfocyanate medication as previously taken.

Four months before entry he noted a sense of dizziness and mild headache; at times he felt sluggish. He occasionally had to rest because of a feeling of mild chest oppression and an occasionally associated feeling of breathlessness. At that time he was taking aminophyllin, 3 gr. three times a day. Physical examination was unchanged except that the blood pressure was 230 systolic, 130 diastolic. The fluoroscopic examination was repeated and revealed a large left ventricle and a dense aorta; the lung shadows were normal. An electrocardiogram showed a normal rhythm of 75, moderate left-axis deviation and a slight diphasic T₁.

Six weeks prior to entering the hospital he developed a mild "nasal" infection, which persisted

to the time of admission without variation in degree, accompanied by occasional slight elevation of temperature. One week before entry the feeling of chest oppression became more severe, exertional dyspnea developed and the patient felt "wheezy" at night.

Physical examination revealed a well-developed and well-nourished man in mild respiratory distress suffering with a mild upper respiratory infection. Examination of the heart showed the maximum apical impulse to be 11 cm. to the left of the midsternal line in the fifth intercostal space. The heart sounds were regular and of fair quality. At the base of the heart over the aortic area a moderately loud, slightly harsh systolic murmur was audible. To the left of the lower sternum a very soft blowing diastolic murmur was heard. At the apex of the heart a moderately loud slightly coarse systolic murmur and a diastolic third heart sound were heard, and these carried toward the lung base. Rales were audible at both lung bases posteriorly. The abdomen was flat and soft, and the lower edge of the liver, which was tender, was felt two fingerbreadths below the costal margin. No other abdominal masses were felt. There was no ankle edema.

The blood pressure was 200 systolic, 110 diastolic. The temperature was 99°F., the pulse 78, and the respirations 20.

The examination of the blood revealed a hemoglobin of 12.4 gm. and a white-cell count of 5100 with 82 per cent polymorphonuclears, 12 per cent lymphocytes and 6 per cent monocytes. The blood Hinton test was negative. The non-protein nitrogen was 28 mg. per 100 cc. The urine had a specific gravity of 1.010, was acid in reaction and gave a + test for albumin; the sediment contained a rare hyalin cast, 4 red cells and 1 white cell per high-power field. An electrocardiogram showed a normal sinus rhythm, with a rate of 60. T₁ and T₂ were inverted and sagging; T₄ was rather sharply inverted; and there was a moderate amount of left-axis deviation. An x-ray film of the chest demonstrated that the heart lay horizontally in the chest and that there was considerable enlargement of the left ventricle. The curve of the ventricle was prominent and the apex was blunted. The aorta was tortuous and prominent in the region of the knob and showed some calcification in its walls. There was also a slight bulge of aorta near the root. The lung fields were clear.

Three days after admission the patient noticed a slight amount of blood on his pajamas. This was attributed to congestion of a hyperplastic prostate.

After ten days the patient improved with and digitalis. His apparent upper-respiratory infection subsided, and he was at-

get about satisfactorily without great discomfort. He left the hospital in the late afternoon.

Second admission (12 hours later). The patient returned to the hospital because of midepigastria discomfort, nausea and vomiting which had developed a few hours after a rather heavy supper. There was no substernal or back pain. The patient was obviously uncomfortable and was sweating. The examination of the heart revealed good heart sounds, a regular rhythm and murmurs as previously noted. Good vessel pulsations were felt in the legs. The lungs were normal. There was tenderness and some spasm over the entire abdomen, most marked on the right side, opposite and above the umbilicus. The tenderness was less striking in the right lower quadrant. The liver did not appear to be enlarged. There was questionable tenderness over the gall bladder. The peristaltic sounds at times seemed diminished. The rectal examination was negative except for slight enlargement of the prostate.

The blood pressure was unchanged, 200 systolic, 110 diastolic. The temperature was 99°F., the pulse 50, and the respirations 25.

The white-cell count was 20,000. The urine examination was negative except that the sediment contained 3 white cells per high-power field. An electrocardiogram was similar to the previous ones.

The patient was operated on two hours after admission.

DIFFERENTIAL DIAGNOSIS

DR. T. D. JONES: The initial complaint suggests that the patient had coronary disease and a decrease in his cardiac reserve. One soon learns that he had persistent hypertension, the pressure remaining elevated at every determination over a period of fourteen years. There is little evidence that potassium sulfocyanate had any ameliorating effect. Dizziness, headaches, and ringing in the ears may be taken as a part of his hypertensive syndrome. Broken conjunctival blood vessels also occur in hypertensive patients.

Although the stature of the patient is not described, it is assumed that he was of average size. As would be expected, the heart was distinctly enlarged, and there was left-axis deviation by electrocardiogram. Initial fluoroscopy verified the clinical impression of hypertensive heart disease in a patient with definite arteriosclerosis, at least of the thoracic aorta. The murmurs described are not especially unusual in a patient with hypertension and arteriosclerosis. In a patient with these findings, a sense of oppression in the chest warrants a diagnosis of angina pectoris — and a consideration of the presence of coronary sclerosis. This was considered to exist, since he was given anti-anginal therapy. There is no definite indica-

tion that it was beneficial. Breathlessness was probably associated with the decrease in cardiac reserve.

For a few months prior to admission and especially for the preceding six weeks, there was an apparent increase in symptoms. On admission there was evidence of mild congestive heart failure, along with an increase in the feeling of chest oppression. This failure may have been precipitated by the recent mild respiratory infection that was thought to have persisted to the time of admission. The exact nature of the respiratory infection is impossible to determine in retrospect.

Failure was indicated by respiratory distress, slight enlargement of the liver, rales in the lung bases, and concomitant urinary changes. There was an obvious increase in the severity of the heart disease over previous examinations as indicated by the heart size. This is not surprising in view of the persistent hypertension and the story of slowly diminishing cardiac reserve. It is rather surprising that there was no evidence of actual renal disease after so many years of hypertension.

The murmurs are distinctly in keeping with the hypertensive and arteriosclerotic process and need not raise the question of rheumatic valvular disease. There was no evidence of aortic stenosis; syphilitic aortic disease seems unlikely in view of his age, the negative Hinton test, the absence of a syphilitic history and the prolonged period of symptomatology. A diastolic murmur resulting from syphilitic aortitis usually develops prior to symptoms, rather than after a long period of decreased cardiac reserve resulting from this condition.

The electrocardiograph was not too helpful. The changes raise the question of a previous slow occlusion of the coronary vessels. This suggestion must remain as a possibility despite no history of an acute coronary episode. The sharply inverted T₁ is suggestive, and certainly corroborates the impression of extensive heart disease.

The x-ray findings reiterate the question of the presence of sclerotic changes, at least in the ascending aorta. In view of the terminal episode the question naturally arises whether or not the arteriosclerotic process was more progressive than was apparent.

The question of finding blood on the patient's pajamas is confusing and does not help clarify the underlying process. As reported it is impossible to connect it directly with the patient's illness.

The second and final admission, twelve hours after hospital discharge, seems unquestionably a problem of an acute abdominal condition. In view of the previous history and findings, one would naturally expect the episode to be related to the hypertensive and arteriosclerotic syndrome, espe-

cially the latter. The acute symptoms began three or four hours prior to readmission to the hospital, and evidently were not too severe, otherwise immediate surgical intervention would have ensued. It would be helpful to know what happened to the blood pressure during this period, as it is distinctly lowered as the result of appreciable hemorrhage, of dissection of an arterial aneurysm and of acute coronary closure. So far as I am aware, it may or may not be lowered in mesenteric thrombosis. However, on admission the pressure was very near its previous high level.

Apparently there was no chest pain to suggest acute coronary closure, nor was shock so severe as one might expect in extensive hemorrhage or extensive aneurysmal dissection. Also against the latter is any indication of direction of dissection, usually suggested by the radiation of pain. It hence seems more likely that thrombosis or infarction of the mesenteric vessels comes nearer satisfying the general features presented by the abdominal emergency. Mesenteric thrombosis therefore is my preoperative diagnosis. This would not be too unusual in a person with long-standing hypertensive heart disease and coronary sclerosis, with some question of previous coronary closure. It seems likely that arteriosclerosis was the fundamental basis for the difficulty.

DR. PAUL D. WHITE: I saw this man in 1931 on two occasions because of his hypertension. He was apparently symptom-free at the time. He did not have an aortic diastolic murmur but only an aortic systolic murmur, which, because of his hypertension, I was inclined to think was not due to valvular disease. Dr. Edward Bland later raised the question whether the aortic systolic and diastolic murmurs were of rheumatic origin. He simply raised that question, but it is unlikely that at this patient's age there had occurred sufficient additional rheumatic disease to produce an aortic diastolic murmur.

A PHYSICIAN: In the presence of extensive calcareous valvular disease, could there be some degree of regurgitation?

DR. WHITE: I think that is more of a possibility here than rheumatic involvement, if there is any valvular disease at all.

A PHYSICIAN: Is not the story different from that of aortic stenosis of significant degree? Would you not expect him to have died sooner?

DR. WHITE: No. A good many patients do have acute failure,—left ventricular failure,—but not until ten or more years after the accidental finding of a murmur undoubtedly due to aortic stenosis. They can even live some years after the heart failure starts, despite a high degree of aortic stenosis.

DR. JONES: Can such a systemic pressure be sustained with aortic stenosis?

DR. WHITE: Yes, it can be done. I have seen a number of such cases.

DR. ERNEST M. DALAND: If you could have seen this patient yourself it would have been obvious that he had an acute abdominal condition with his maximum tenderness and spasm in the right upper quadrant, just above the umbilicus. There was questionable tenderness over the gall bladder, but he gave no history of previous gall-bladder disease or ulcer. Although he had a good deal of rigidity in the right upper quadrant, he did not have a board-like belly and a perforated ulcer was ruled out on that basis. He did not have enough localized tenderness over the gall bladder to make a diagnosis of acute cholecystitis. The possibility of appendicitis was considered. It seemed as if his acute abdominal condition must have had some relation to the previous illness, and so the diagnosis of mesenteric thrombosis was thought most likely. Under general anesthesia the abdomen was opened through a rather high midline incision. We found the appendix and gall bladder free of disease, and the liver was normal. The chief finding was a large retroperitoneal hematoma. This was below the level of the pancreas, at the root of the mesentery of the small bowel. It looked somewhat like an acute hemorrhagic pancreatitis except that there was no fat necrosis and we were able to palpate the pancreas separately from the mass. The mass was 8 to 10 cm. in diameter. The intestines showed good color, and no mesenteric thrombosis was found. We could not feel any aneurysm, and no further exploration was made. The postoperative diagnosis was retroperitoneal hemorrhage. The patient made a good recovery from operation. At the end of the operation his systolic blood pressure was down to about 100, but during the next few hours it returned to 200 and he felt quite well during the remainder of the day. He asked what the operative findings were and discussed the diagnosis quite intelligently. About four o'clock the next morning, about twenty-four hours after the operation, he suddenly went into collapse and was dead in a minute or two.

DR. TRACY B. MALLORY: At operation, a large retroperitoneal hematoma was found, source not determined. Does anyone care to speculate any further on the diagnostic possibilities?

DR. JONES: I presume he had an aneurysm that ruptured into a closed space. That changes the diagnosis from probable mesenteric thrombosis to a dissecting type of lesion.

DR. WHITE: Do you think it was necessarily a dissecting aneurysm? Could it have been hem-

orrhage from a saccular arteriosclerotic aneurysm of the abdominal aorta?

CLINICAL DIAGNOSIS

Mesenteric thrombosis.

DR. JONES'S DIAGNOSES

Hypertensive heart disease.

Coronary sclerosis.

Mesenteric thrombosis.

ANATOMICAL DIAGNOSES

Acute hemorrhagic pancreatitis with fat necrosis.

Retroperitoneal hematoma.

Slight hemoperitoneum.

Cardiac hypertrophy.

Arteriosclerosis: marked, aortic; moderate, pulmonary and coronary.

Nephritis, vascular, chronic.

Pulmonary edema.

Operative wound: exploratory laparotomy.

PATHOLOGICAL DISCUSSION

DR. MALLORY: We had considerable difficulty at the time of autopsy in determining the cause of the hemorrhage. The great bulk of the hematoma lay in the mesentery, which had been dissected into two leaves by the blood. Tracing this back we eventually tracked it down to the posterior surface of the head of the pancreas, where we found numerous areas of fat necrosis. At this point there was characteristic acute hemorrhagic pancreatitis, so-called "pancreatic apoplexy." A peculiar feature was that the blood instead of dissecting profusely through the pancreas had dissected largely into the root of the mesentery. The pancreatitis was limited to the posterior portion of the head of the pancreas. The body and tail were normal. It would not have been possible to recognize it at the time of operation because it was not until we approached the organs from behind that we found it ourselves.

The other findings were a markedly hypertrophied heart, weighing 550 gm. The coronary arteries were large and capacious with some arteriosclerotic plaques but no occlusion at any point, and the myocardium showed no areas of infarction. The aortic valve was entirely negative. There was no calcification, no stenosis or no regurgitation. The kidneys showed the characteristic nephrosclerosis to be expected in long-standing hypertension.

DR. WHITE: There are two things I should like to emphasize with respect to this case. First, there can be long-standing aortic systolic murmurs and even aortic diastolic murmurs without valv-

lar disease. Second, the electrocardiogram of a large hypertensive heart can closely resemble that of coronary heart disease.

DR. MALLORY: The ascending aorta was markedly sclerotic. So far as thrombosis is concerned there was no gross calcification but a little dilatation, and the aortic ring itself was of normal measurement.

DR. DALAND: Do you not think it surprising that no more was found in the pancreas at the end of thirty hours?

DR. MALLORY: It is very unusual.

CASE 28512

PRESENTATION OF CASE

First admission. This forty-four-year-old man was admitted because of a persistent cough.

One year prior to admission the patient developed a cough, which at times was productive of a slight amount of gray-white sputum. When he coughed he occasionally had substernal pain, but this was never severe. Four months before entry the cough increased and a greater amount of sputum was raised; this was thick and yellow but did not have an odor and never contained blood. At that time both ankles became swollen and stiff. His physician said that the edema was not of a "pitting type" and that the urine was normal. Despite the medication provided the cough was unimproved. The leg edema gradually increased to the knees, the ankle stiffness became more marked, and the knees became stiff, swollen, painful and slightly red. He also developed exertional dyspnea. During the entire period the cough became progressively worse.

One week before admission an electrocardiogram was said to have been normal. A chest roentgenogram disclosed some cloudiness in the lower left lung, but no diagnosis was made. A single sputum was negative for acid-fast bacilli. He was treated with "wheat-germ oil" injections, and two days later the joint pain and most of the leg swelling disappeared. During the week prior to admission he raised one fourth of a cup of sputum each day, which was very thick and had developed a foul odor. During the six months prior to entry he had lost 27 pounds.

The patient's mother died of "carcinoma of the throat," and his father died of heart trouble. The past history was noncontributory.

Physical examination revealed a prematurely gray man who was hoarse and who coughed frequently making him uncomfortable because of the associated chest pain. The heart was percussed 10 cm. to the left of the midsternal line. The heart sounds were of good quality, and no murmurs

were heard. There was decreased expansion of the left chest, with dullness over the upper left chest anteriorly and increased breath and voice sounds in this area. Scattered fine rales were audible at the left apex, and a friction rub was heard in the left midaxillary line. Examination of the abdomen was negative. There was swelling with some pitting edema of both lower legs. The ankles were slightly swollen but were not warm, red or tender. There was marked clubbing of the fingers and toes.

The blood pressure was 120 systolic, 70 diastolic. The temperature was 101°F, the pulse 95, and the respirations 30. The temperature and pulse continued to rise each evening.

Examination of the blood revealed a hemoglobin of 91 gm, a white-cell count of 20,800 with 88 per cent polymorphonuclears. The urine repeatedly was acid in reaction, had a specific gravity of 1.028 and gave a + test for albumin; the sediment contained 7 red cells and occasional white cells and epithelial cells per high power field. The blood Hinton test was negative. The blood protein was 59 gm per 100 cc, with 28 gm albumin and 31 gm globulin, making the albumin globulin ratio 0.9. The sputum examination was negative for acid fast bacilli on two occasions. A chest roentgenogram showed diffuse hazy density of the entire left lung field, and within this area there was a fairly sharply defined rounded mass lying posteriorly against the ribs and extending from the fourth to the eighth rib. There are multiple areas of rarefaction within this mass, and there were similar areas of rarefaction anterior to it in the right upper lobe. The mediastinum was displaced to the left. The left side of the diaphragm was high, and the left costophrenic angle was obliterated. There was no evidence of disease in the right lung, and the visible ribs and vertebrae showed no evidence of metastases.

On the third day after admission the patient was bronchoscoped. There was no widening of the trachea or fixation of the carina. At a point in the left bronchial tree about 5 or 6 cm below the carina the left main bronchus became narrowed and presented an irregular granular appearance on the lateral as well as the medial aspect. The left upper lobe orifice was not seen. Foul bloody secretion was aspirated, and several biopsy specimens were taken, which were reported as showing acute and chronic inflammation. On the ninth hospital day a left upper lobe abscess was drained posteriorly by resecting segments of the fifth, sixth and seventh ribs. The abscess was described asummense. It contained a moderate amount of gangrenous lung and small amounts of pus. It was traversed by several septums. Sulfanilamide pow-

der was implanted locally. A pleural biopsy was reported as showing acute and chronic pleuritis. The culture of the pus demonstrated a few alpha hemolytic streptococci and a moderate growth of nonhemolytic streptococci. After operation, the patient improved and the temperature and pulse returned to normal. He was discharged on the thirty-third day after admission.

Second admission (one month later). The patient was readmitted for study of the persistent ankle edema. After discharge there was little drainage from the chest. One week before entry the cough was slightly increased but little sputum was raised. Since the previous admission he had suffered with a great deal of exertional dyspnea but at no time was he orthopneic.

On examination the patient was plethoric and puffy faced, and coughed frequently. The neck veins were not distended. The trachea was slightly deviated to the left. The heart was percussed 8 cm to the left of the midclavicular line. The sounds were regular and of good quality. There seemed to be a split second sound audible at the apex. No murmurs were audible. There was a large cavity in the left posterior chest, from which a small amount of foul pus drained. Bronchial whistling was audible over this area. The left chest was dull on percussion. The abdomen was held tensely, however, no fluid was found and no masses were definitely felt. There were dilated veins in the lower abdominal wall. Clubbing of the fingers and toes was again noted. There was no evidence of phlebitis.

The urine and blood examinations were similar to those noted during the previous admission. The nonprotein nitrogen was 14 mg per 100 cc, the chloride 98.8 milliequiv per liter, and the protein 55 gm per 100 cc, with an albumin of 30 gm and a globulin of 25 gm, giving an albumin globulin ratio of 1.2. An electrocardiogram showed a normal sinus rhythm with a rate of 90. The PR interval was 0.16 second, T₁ was flat, and T₂, T₃ and T₄ were upright. The Congo-red test showed 100 per cent retention of the dye in the serum after one hour.

He was treated with a course of sulfathiazole, totaling 12 gm in four days, and was discharged unimproved nine days after admission.

Third admission (two months later). The patient was readmitted because of painful swelling and stiffness of the knees and ankles, which developed soon after leaving the hospital. The pain was dull and occurred intermittently each day, being worse in the morning, but at no time was it severe. The joints were not red or warm. During the three weeks prior to admission the pa-

tient had gained 10 pounds. The chronic cough had persisted, and occasionally there was blood streaking of the sputum. While at home he took sulfathiazole, which was later changed to sulfadiazine because of nausea, "dizziness" and the development of a rash on the face. He had nocturia, one or two times, and occasional urgency. He had not had any fever or rise of blood pressure.

Physical examination was similar to that already noted except that there was swelling of the ankles without redness, tenderness or pitting edema. There was no pain or limitation of leg-joint motion.

Examination of the blood revealed a hemoglobin of 10.7 gm. and a white-cell count of 20,300 with 64 per cent polymorphonuclears. In the smear the red cells appeared normal, and the platelets were slightly increased. The nonprotein nitrogen was 30 mg., and the protein 7.2 gm. per 100 cc. No acid-fast organisms were found in the sputum. The urine had a specific gravity of 1.010 and gave a + test for albumin; the sediment contained 15 white cells, a rare red cell and 3 epithelial cells per high-power field; the pH was alkaline on three occasions and acid on two. A phenolsulfonephthalein test showed 17, 8, 12 and 15 per cent excretion of the dye in a quarter, a half, one and two hours respectively. A chest film showed little change in appearance since the last entry. The greater portion of the left upper lobe was honeycombed in appearance, showing numerous small cavities. The large abscess cavity was no longer definitely visible. The fluid in the left base had cleared. There was some inspiratory shift to the left, and the mediastinum was displaced to this side. The right lung field remained clear.

The patient was treated with 4 gm. of sulfadiazine and discharged unimproved on the third day after admission.

Fourth admission (two months later). The patient was readmitted for left pneumonectomy. Since discharge he had gained weight but continued to have cough and hemoptysis. He became dyspneic on climbing a flight of stairs. Ankle edema had not been severe.

Physical examination was similar to that of previous admissions.

The temperature was 98.6°F., the pulse 80, and the respirations 22.

The hemoglobin was 9.8 gm., and the white-cell count 16,900 with 65 per cent polymorphonuclears. In the smear the red cells were fairly normal, but the platelets were slightly increased. The urine was acid in reaction, had a specific gravity of 1.012 and gave a + test for albumin; the sediment contained 2 hyaline casts, occasional finely granular casts, 15 red cells, 15 white cells and 2 epithelial

cells per high-power field. A phenolsulfonephthalein test showed 23, 20, 20 and 10 per cent excretion of the dye in a quarter, a half, one and two hours respectively. The nonprotein nitrogen was 18 mg. per 100 cc., the protein 5.9 gm., and the sulfadiazine level 5.9 mg.

A 7-gm. course of sulfadiazine was administered in the five days after admission.

An operation was performed on the eighth day after admission.

DIFFERENTIAL DIAGNOSIS

DR. JOHN W. CASS: This history could be compatible with a number of things; it raises the question of tuberculosis, abscess and some type of bronchial obstruction with slowly increasing infection. The suggestion of swollen joints and the edema cannot be evaluated as yet with the mere facts of the history. They do suggest pulmonary osteoarthropathy with some evidence of cardiac or renal failure. There is definite evidence of pulmonary disease in the x-ray films of the chest, and little evidence of congestive failure.

I do not know why "wheat-germ oil" was given. I certainly should like to know if anyone cares to offer the information.

DR. JOSEPH C. AUB: We have tried it out in cancer with equivocal results; it contains a large quantity of vitamin E. I had nothing to do with its use, however, in this case.

DR. CASS: The pulmonary process became contaminated with mouth organisms, and undoubtedly there was abscess formation, which raises the question whether it was abscess from the beginning. I should doubt this from the sequence of events; I think that the primary disease process simply became contaminated with these organisms and that abscess formation occurred.

Extreme loss of weight is compatible with lung abscess or other suppurative lung conditions, as well as tumor, malignant or benign, with or without infection.

Apparently the patient was having real pain, which is against tuberculosis and more compatible with abscess or tumor. Was more than one sputum specimen examined for tubercle bacilli?

DR. TRACY B. MALLORY: At least three sputum examinations were negative for tubercle bacilli.

DR. CASS: I think we can feel fairly confident that we are not dealing with tuberculosis. Although clubbing can occur very quickly under certain conditions, its sudden development is rare; it points against tuberculosis but is perfectly compatible with tumor plus infection or suppurative infection alone.

The physical signs I interpret as those of solid mass, with peripheral atelectasis and pleural in-

involvement as the explanations why he was having so much pain.

I should say that the edema was not associated with the heart but with kidney involvement secondary to the septic process in the chest. The urine showed evidence of kidney irritation. The serum protein was a trifle low, the albumin definitely low; the ratio was inverted so that although the total protein was not greatly below normal I think it is still compatible with sufficient kidney damage to cause some degree of edema.

May we see the x-ray films?

DR. LAURENCE ROBBINS: The entire process is on the left. This is the large cavity that is spoken of; the other areas of density in the large cavity are seen better in the lateral view and lie anterior to the large cavity. The right lung field is clear.

DR. CASS: The x-ray findings strengthen our belief that we are not dealing with tuberculosis or pure infection of any type. There is a distinct description of a mass, and it is well known that any type of malignant mass in the chest can have cavities within it or behind the obstruction that the mass causes. From the bronchoscopist's report we get confirmation of bronchial obstruction with suppurative disease in back of the obstruction. The only infectious state that would produce this would be tuberculosis with involvement of the bronchial wall as well as the parenchyma. But we have several negative biopsies, which are quite important in ruling out tuberculosis but not tumor. As a matter of fact the appearance of bronchial tuberculosis is so characteristic that the bronchoscopist would scarcely need to take a biopsy. We have not ruled out malignant tumor, however, on the basis of the negative bronchoscopic examination and biopsies.

It was apparently obvious that the suppurative situation could not be adequately drained by postural or bronchoscopic drainage, and external drainage had to be instituted.

This apparently changed the course very little, and it was necessary to readmit the patient after a month, primarily for study of his edema. His heart seemed essentially normal, and I believe his dyspnea was chiefly mechanical, perhaps due to displacement of the mediastinum. He then had a bronchial fistula, as would be expected, and no essential change in the primary disease. I still believe that the edema was secondary to the pulmonary disease. I do not attach any particular significance to the abdominal veins, in spite of the fact that they might indicate liver damage. The non-protein nitrogen was within normal limits—a bit low. The total protein was low, and the albumin-globulin ratio essentially normal. Even though

this is true, the lowered total protein was getting to the point where one would expect edema. So far as the Congo-red test goes, this rules out amyloid disease. It is rather strange how seldom one makes a clinical diagnosis of amyloid disease in suppurative diseases of the chest, but I am not sure how much significance can be placed on a perfectly normal Congo-red test.

At the third admission the patient apparently had improved a bit, unless the gain in weight was due to edema. But I believe it was probably a true gain in weight. The persistent pain I think is adequately explained as pulmonary osteoarthropathy, and he still had edema. It is apparent that the drainage was not adequately taking care of the pulmonary situation. He had reached the point where as much as possible had been gained by the drainage, and an attempt was made to correct the primary situation.

He was admitted for the fourth time for operation, pneumonectomy. It is definite that there were bronchial obstruction and pulmonary suppuration with multiple cavities, and the question is whether we can explain this process on the basis of infection alone, of tumor or of some other form of bronchial obstruction plus suppurative disease behind the obstruction. It is possible, I suppose, to have a lung abscess beginning with such a type of history as this with a gradual development of foul sputum. I cannot visualize, however, a bronchial obstruction occurring secondary to abscess, and we know from bronchoscopy that obstruction was present. The only infection that would fit the picture is tuberculosis, but we have definitely ruled out tuberculosis by the multiple sputum examinations and by the biopsy. If this man had been fortunate enough to have had tuberculosis this series of procedures would have been proper,—namely, the drainage of a large cavity and, later, a pneumonectomy,—but I believe he was not so fortunate as to have this disease. So we are left with tumor with abscess formation behind the obstruction. The tumor could be benign, but we do not have the proper history for a benign tumor. There was not the long story of cough and intermittent episodes of infection so commonly associated with this type of obstruction. A tumor was not seen on bronchoscopic examination, and although it is more or less guesswork from this point on, I should say that we are dealing with a malignant type of obstruction, in spite of the negative biopsies. The course was certainly relatively benign for the usual bronchiogenic carcinoma. We have a right to mention primary sarcoma—a very rare tumor and one that may very well fail to yield a positive biopsy. However, I think we should pick the commoner type of disease, which

is bronchiogenic carcinoma, in spite of the history of repeatedly negative biopsies.

DR. WILLIAM B. BREED: I cannot refrain from suggesting lymphoma as a strong possibility for no good reason except bitter experience in the past.

DR. JOHN W. STRIEDER: As Dr. Cass said, certainly the sequence of steps was correct and one has the right to suspect underlying disease—I certainly agree with Dr. Cass that carcinoma is the best bet.

CLINICAL DIAGNOSES

Carcinoma of lung, with necrosis and abscess formation.

Sulfonamide nephrosis.

DR. CASS'S DIAGNOSES

Carcinoma of the lung (bronchiogenic).

Bronchial obstruction, with pulmonary suppuration.

Nephrosis (septic).

Pulmonary osteoarthropathy.

ANATOMICAL DIAGNOSES

Epidermoid carcinoma of lung.

Abscess of lung.

PATHOLOGICAL DISCUSSION

DR. MALLORY: Two interesting features invite discussion—the primary pulmonary process and the edema and the signs in the urine. Since we did not get permission for an autopsy, I cannot say anything about the kidneys, and I suppose it is profitless to speculate about them. In regard to

the lungs, total pneumonectomy was done with a preoperative diagnosis of chronic lung abscess, but with the consideration that there might possibly be carcinoma behind it. Inasmuch as they were not able to prove the presence of carcinoma, it was believed that the patient should be given the benefit of the doubt and the chance of cure by pneumonectomy.

At the time of operation it became evident as the operation progressed that the surgeon was forced to cut through neoplastic tissue close to the hilus of the lung. He had to continue at that stage with the pneumonectomy, which was successfully carried out. The operative wound healed well, with complete apparent relief of the pulmonary symptoms, but the patient slowly developed further evidence of renal insufficiency and died three weeks after operation.

The lung showed a large abscess cavity near the base of the upper lobe. The walls of this cavity consisted primarily of fibrous tissue and showed no neoplasm. Above this major abscess cavity, however, was a spherical tumor mass, in the midst of which was a second abscess cavity, and the walls of this upper cavity were neoplastic. The major abscess that was seen in the x-ray plates was, I believe, the lower benign one. That is what was drained at the first operation, and no tumor was encountered at that time. Nor was any found there when we finally had the entire lung in our possession. The bronchus leading to this area was occluded by external pressure from extension to the hilus of the tumor, which originated near the apex of the lung. The tumor was a poorly differentiated epidermoid carcinoma.

HOSPITALS AND COMPULSORY HOSPITAL INSURANCE

"EVERY governmental energy must be concentrated on winning the war. Reforms or making America over cannot but dislocate the war effort." This statement by Ex-President Hoover in his twelve points of vital interest to the Home Front is so axiomatic that it should delay additional social-security legislation until the war has been won. Regardless of its virtues or defects, legislation that will profoundly affect the postwar American way of life should be postponed for consideration with other peacetime readjustments. However, since bills of this type have already been submitted to Congress and since silence might be taken for assent or approval, discussion appears to be necessary.

Such a bill, "To amend and extend the provisions of the Social Security Act; to establish a federal social-insurance system; to extend the coverage of federal old-age and survivors' insurance; to provide insurance benefits for workers permanently and totally disabled; to establish a federal system of unemployment compensation and temporary disability benefits and a federal system of unemployment offices; to establish a federal system of hospitalization benefits; to amend the Internal Revenue Code; and for other purposes," has been introduced by Representative Thomas H. Eliot, of Massachusetts. Without consideration or comment on the other parts of the bill, the proposal "to establish a federal system of hospitalization benefits," or, in other words, "compulsory hospital insurance," as it is commonly called, deserves critical comment.

At the present time in the United States there is a widespread and rapidly growing system of voluntary hospital insurance known as the Blue Cross Plan. The basic philosophy underlying such voluntary hospital insurance is radically different from that of compulsory hospital insurance, in spite of their aiming at the same objective.

Voluntary insurance, as its name implies, connotes a voluntary act on the part of the insured, as the result of consideration and decision. It requires thinking. Thus it exemplifies the essence of democracy. By thinking, choice and action the subscriber becomes a better citizen, and by the development of his will and initiative the community is benefited and improved. It is a slow process, but sure.

Compulsory insurance, likewise, is self-descriptive for it means that all persons falling within its provisions shall, willy-nilly, comply with its regulations. There is no opportunity for choice or decision. Essentially it is taxation under another name. It is regimentation held to be justifiable by the claim that it is for the benefit of the insured, that it spreads the burden and that it forces the improvident to provide. Its proponents claim that it will achieve in one year what voluntary insurance would require many years to accomplish

and that it would eliminate charity and so increase the self-respect of former recipients. They compare by analogy the anticipated benefits of compulsory hospital insurance to the good accomplished by the Workmen's Compensation acts, forgetting that in the latter case no voluntary plan was available.

Voluntary hospital insurance has been available for ten years. New and not understood, growth during the early years was slow. It has rapidly expanded during the last five years, and now over ten million people are insured under this plan. It is spreading rapidly. Reciprocity between plans is accepted in principle and practice. In collaboration with state and local medical societies, plans for the coverage of medical fees for hospital care are being developed, and in some states are already in operation. Since it operates within state boundaries, it is adaptable to local conditions. Since it is a nonprofit corporation, it is flexible and can adjust to new conditions without resort to legislation. Since it is subject to regulation by state commissions of insurance and welfare, its subscribers are protected from exploitation. Its cost of operation has been uniformly low.

There is no opposition on the part of the American Hospital Association or of most hospital administrators to the provision of better hospitals in rural areas, to the extension of hospital care for certain public-assistance categories, such as the aged, and even to the consideration of compulsory hospital insurance. But they believe that the resulting plan should be the product of collaboration and co-operation by the Social Security Board, hospital representatives, physicians and representatives of the charitable, labor and welfare organizations of the community and that this collaboration should take place at a time when adequate and contemplative consideration can be given to a problem so vitally affecting American life. The American Hospital Association is actively furthering the extension and liberalization of Blue Cross plans, an endeavor that can go on during the emergency without hampering the war effort, since

the methods and machinery are already in operation.

Specific defects in the Eliot bill can be noted as follows:

The proposed federalization scraps the present relation provided by the Social Security Act between the states and the federal government.

The United States is too large and too varied to be adequately legislated for on a matter so vitally influenced by local conditions. States can give better adjustment and control, according to local needs.

The bill requires the setting up of a new bureau for administration and operation at a time when the manpower of the Nation is already overextended, and with the certainty of added cost.

Nothing in the bill remedies the lack of medical care and hospital facilities in rural areas. In fact, the bill expressly prohibits the use of money for this purpose.

The bill does not adequately separate administration and payments for hospitalization and disability benefits. The experiences of European plans point to the necessity of this separation.

The bill as drawn gives no consideration to the necessity of preserving voluntary plans. The present hospital system is based on the co-operation of voluntary and governmental hospitals, which supplement each other in caring for all classes of the community. If compulsory insurance is instituted, certainly a similar co-operation should be provided for with voluntary insurance. Otherwise it will probably mean the gradual destruction of philanthropy, for local interest will be difficult to sustain if the federal government assumes leadership and responsibility. Local morale suffers under remote control, and there would be no incentive for experimentation in different localities to meet varying conditions.

There is no consideration of medical-care fees, a program that is now going forward under the leadership of the voluntary plans.

The problem boils down, finally, to an evaluation of the moral values inherent in voluntary plans contrasted with the expected material values of compulsory plans. It is essentially individualism versus regimentation. Further consideration of such social readjustments should not be undertaken during the stress of war conditions, but should be put off for consideration after the war is won. Probably a satisfactory compromise between the two extremes can then be obtained.

DIPHTHERIA CARRIERS

THE care of the diphtheria carrier has been a perplexing problem for the last fifty years. So many different measures have been heralded as effective and have later been found to be valueless that one is wary of any

ward. It has long been known that the hazard of the tonsillar carrier is usually eliminated by tonsillectomy. Furthermore, the removal of a small ball of cellophane or a piece of rubber sponge from a child's nose has promptly brought about a series of negative release cultures. However, when tonsils have been removed and the question of a foreign body in the nose has been eliminated, the experienced physician has learned that other measures aimed at the destruction of the diphtheria organism not only have proved to be futile but have made matters worse by injuring the mucous membrane.

A valuable contribution to the carrier problem has been made by Boissard and Fry* in England. From an elaborate and painstaking study of 388 cases of diphtheria, these authors have found that the presence of substantial numbers of hemolytic streptococci in the nose was frequently responsible for the persistence of positive diphtheria cultures and that, by elimination of the streptococcal element with local applications of sulfanilamide, the diphtherial element promptly disappeared. No drug of the sulfanilamide group has been shown to have a direct influence on *Corynebacterium diphtheriae*, either in vivo or in vitro; therefore, these drugs have no effect on the course of diphtheria. The administration of antitoxin still remains the first principle in the treatment of the disease, but it is of no value in the treatment of the healthy carrier. Indeed, the value of antitoxin in treatment of the disease does not depend on any direct action on the diphtheria organism but on the neutralization of the circulating toxin; this permits the natural protective forces of the body to attack the localized infection effectively. The internal administration of sulfanilamide, as well as its local application, has been tried on carriers, but with unsatisfactory results. These English authors, however, have proved that the drug is effective in nasal carriers in whom *C. diphtheriae* is associated with substantial numbers of hemolytic streptococci.

The treatment consists in insufflating sulfanila-

mid powder into the nose twice a day for a week. During the following week, cultures are taken every other day. If all these are negative, the patient is released; otherwise, the process is resumed for another week. These authors obtained abrupt and permanent elimination of the diphtheria-carrier state in 24 of 26 nasal carriers after the first week's treatment. In 8 cases of tonsillar carriers, the insufflation of sulfanilamide in the nose and its direct application to the tonsils proved ineffective.

The scholarly attitude exhibited in the report of this experiment offers convincing evidence that a significant step, with well-defined limitations, has been made in the elimination of the diphtheria carrier.

MEDICAL EPONYM

SIPPY TREATMENT

The first account by Dr. Bertram W. Sippy (1866-1924), professor of medicine in the Rush Medical College, of his method of treating peptic ulcer appeared in the third volume (pages 342-353) of *A Handbook of Practical Treatment* (Philadelphia and London, 1917), edited by John H. Musser and A. O. J. Kelly. He writes:

... Undoubtedly, hyperchlorhydria is unfavorable to the healing of ulcer. . . . The indication in medicinal treatment should be to reduce the corrosive action of the gastric juice, to diminish the mechanical irritation caused by food, pressure, peristalsis, and active movements of the body, to provide adequate nourishment and to treat the symptoms and complicating conditions as they arise. . . . During the first five days no food or drink is given by mouth. . . . At the end of five or six days one may begin to feed half an ounce each of milk and cream every hour from early morning until eight or nine o'clock at night. . . . Midway between each feeding a powder consisting of 10 grains each of calcined magnesia and sodium bicarbonate may be given alternately with a powder of 10 grains each of bismuth subnitrate and sodium bicarbonate. . . .

necessitate the closing of the headquarters of the Society and the office of the *Journal* during the corresponding period. In an emergency, the officers of the Society and the managing editor and associate editors of the *Journal* can be located through their offices or homes.

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1941

TOXEMIA AND ECLAMPSIA

Twenty-seven maternal deaths during 1941 were attributed to toxemia and eclampsia. The term "eclampsia" in this classification applies to pregnant patients who had actual convulsions. Among these patients, there were 7 with convulsions and 1 with a severe toxemia but no convulsions who were delivered by cesarean section. This is noteworthy, since it is generally accepted that undelivered eclamptic patients who are not in labor have the best chance of recovery if they are treated with extreme conservatism. Twenty-five years ago, convulsive patients not in labor were treated by *accouchement forcé*. Because of the extremely high mortality of the patients so treated, manual dilatation of the cervix and subsequent operative delivery gradually came to be frowned on, so that today it is gratifying to note that not one case of eclampsia in this series was so treated. After *accouchement forcé* had been discarded, the belief that emptying the uterus removed the cause of disease and thus enhanced the patient's chance of recovery led to a very general adoption of cesarean section as the treatment of this complication. That any operative interference was ill advised was first brought out by the Stroganoff method of treating eclampsia. Some modification of this conservative method has been proved to be the accepted method of procedure. In some clinics, nothing is done other than sedation of the patient and the intravenous administration of magnesium sulfate—there is no operative intervention. To this conservative treatment, other clinics have added artificial rupture of the membranes for the purpose of inducing labor, and statistics in the clinics where such cases are so handled are so much better than those where cesarean section is done that the latter has been practically abandoned. This being so, it is interesting to analyze the fatal cases of eclampsia delivered by cesarean section.

The first patient was a primipara who died forty hours following a classical cesarean section. The prenatal care was sketchy and probably not ade-

quate. She was about seven months pregnant when three convulsions occurred. A 2½-pound baby, who lived for a short while, was delivered. This case quite probably would not have been fatal had the convulsions been treated symptomatically by intravenous magnesium sulfate, sedatives and, possibly, induction of labor by artificial rupture of the membranes. It is fair to say that the method of treatment in this case would not have obtained in most clinics.

The second case was that of a patient seven and a half months pregnant who had been showing pre-eclamptic symptoms—a systolic blood pressure of 140 and a large trace of albumin in the urine. Because of this she was sent to the hospital for delivery by cesarean section on the following day. During the night the blood pressure rose to 180, and while she was being prepared for operation, a convulsion occurred. A living premature baby was delivered by cesarean section, but the patient did not regain consciousness. In view of the present knowledge of obstetrics, conservatism might have averted this fatality. The prenatal care in this case was adequate if not the most intelligent.

The third case was that of a primipara who had had a previous nephrectomy. She was followed intelligently during the prenatal period but when about thirty-four weeks pregnant developed marked edema and a systolic blood pressure of 180. In spite of hospitalization, the toxemia did not abate; cesarean section was done and a living child delivered. Nine days postpartum convulsions appeared, and death followed within twenty-four hours. Unfortunately there was no autopsy. The late post-partum eclampsia probably means that the remaining kidney suffered permanent damage, which resulted in total kidney failure. In all honesty, it seems unlikely that the cesarean section was much more than a contributing influence in this fatality.

The fourth patient was a primipara approximately at term whose prenatal care was neither intelligent nor adequate. Convulsions occurred before labor, and a cesarean was done because the cervix was not "favorable." Death occurred thirty-six hours after delivery.

The fifth patient had had a previous cesarean section in 1933. She was adequately taken care of prenatally, and at the seventh month was hospitalized because of a systolic blood pressure of 170. Hospital treatment did not relieve the toxemia, and when the patient was about seven and a half months pregnant an extraperitoneal cesarean section of the Waters type was done, but death occurred a few hours after delivery. This patient

may have had myocardial failure, which occurs occasionally in patients with severe toxemia. As she was not in labor and as the membranes had not been ruptured, it is difficult to understand why the Waters operation was performed. In this case, convulsions did not occur.

The sixth case was that of a primipara who, at approximately seven and a half months, developed toxemia associated with vomiting of blood, jaundice and a systolic blood pressure of 220. Hospitalization was recommended and accepted. The morning of the entry the patient's blood pressure came down to 164 systolic, 100 diastolic, but rose to 230 systolic, 120 diastolic in the afternoon. A classical cesarean was done under spinal anesthesia, and a living baby weighing 2 pounds, 12 ounces, was delivered, death occurred shortly after delivery. One can only wonder whether conservatism would have averted this catastrophe.

The seventh patient was a multipara who had had six previous pregnancies and was said to have had toxemia in her second and fourth pregnancies. In the seventh month of her last pregnancy the systolic blood pressure rose to between 160 and 200, and she was hospitalized. Convulsions occurred and increased in severity, and consequently a cesarean section was performed. Death occurred thirty-two hours later. The history of this case is not adequate and, of course, a cesarean section in a multipara with eclampsia has no justification.

The history of the eighth and final case is not adequate. Eclampsia existed in a patient on whom a cesarean section was performed, presumably an autopsy was done because the diagnosis of focal necrosis of the liver was made.

(To be concluded)

DEATHS

FRENCH—RALPH W. FRENCH, M.D., of Fall River died December 7. He was in his sixtieth year.

Born in Fall River, he attended Harvard University and received his degree cum laude from Harvard Medical School in 1910. After serving his internship at the Massachusetts General Hospital he joined the staff of the Truistdale Hospital.

He was a fellow of the Massachusetts Medical Society and the American Medical Association. He was also a member of the American College of Surgeons, the New England Surgical Society and the Fall River Medical Society.

His sister and an aunt survive him.

KENEALY—JOSEPH H. KENEALY, M.D., of Natick died in Chicago, December 2. He was in his sixty-fifth year. Born in Natick, he received his degree from Harvard Medical School in 1900. He practiced in Boston for several years before taking up residence in Chicago. He was a former member of the Massachusetts Medical Society.

His widow and daughter survive him.

WAR ACTIVITIES

CIVILIAN DEFENSE

RED CROSS MOBILE CANTEENS

The following directive was recently forwarded to all regional directors, regional medical heads and deputy regional medical heads of the Massachusetts Committee on Public Safety:

* * *

1. Some misunderstandings may have developed due to the fact that medical mobile canteens were not mentioned in *Medical Handbook No. 2* of the Massachusetts Committee on Public Safety. The Red Cross has agreed to provide a determined number of such mobile canteens properly equipped and with trained personnel that shall become the local units of the Medical Division in supplying civilian war aid, although maintaining their identity and insignia. Should the situation be of such magnitude to require additional assistance, the Medical Division will then call, through appropriate channels, on the Massachusetts Women's Defense Corps, held in reserve for such purposes, or on whatever other supplementary resources are available. Local plans at variance with these terms shall, on request of any party, be submitted to the executive director of the Massachusetts Committee on Public Safety for amendment or approval by him after consultation with the Red Cross.

2. The determined number of mobile canteens varies not merely with the population but with local needs. In some communities one mobile canteen may be sufficient to service two or three towns combining two or three medical first-aid posts, in others the ratio may run as high as one mobile canteen for each medical first-aid post. In the larger cities where several first-aid posts are included in one medical depot, a ratio of 40 per cent of the number of auxiliary ambulances involved is the accepted quota.

3. Auxiliary ambulances accompanying the physicians and their medical units should be the first to arrive at the scene of the incident, but mobile canteens with hot liquids for the treatment of shock should not be far behind.

4. Heretofore, in most localities, mobile canteens have not participated in practice alerts. With the adoption of the audible signal for yellow or green lights, it will now be necessary for these units to mobilize.

It is suggested that plans be developed between chief medical officers and Red Cross liaisons whereby mobile canteens shall proceed to the prearranged spot where they plan to obtain their supply of hot liquids and so forth, and stand by for instructions from the chief medical officer whether to prepare and load such hot liquids, to proceed to the medical depot, medical first-aid post or incident or to dismiss. Where canteen equipment is stored at the medical depot this procedure will be unnecessary in practice alerts, but in any case mobile-canteen vehicles must mobilize on the preliminary audible signal. Chief medical officers must remember they are standing by and not forget to dismiss them.

MISCELLANY

TUBERCULOSIS IN COLLEGE STUDENTS

A second five-year review of tuberculosis in college students, marking the close of a decade of service by the Tuberculosis Committee of the American Student Health Association, reveals heartening progress, along with the stern challenge that tuberculosis still clings tenaciously to first place among causes of death in those of college age. Three hundred and four colleges and universities reported tuberculosis programs for 1940-41 as against one hundred and four in 1936-37, but this represents a bare 36 per cent of American institutions of higher education. Ancient and erroneous notions about tuberculosis still persist in the minds of many college administrators, which unhappily limit the adequacy of their college health services. The truth must be carried to these people ceaselessly and convincingly, if tuberculosis is to be dislodged from the American college campus. The following abstract of a recent article on the subject (Lyght, C. E. Tuberculosis in college students: a second five-year review. *Am. Rev. Tuberc.* 46:227-237, 1942) is of interest.

The Tuberculosis Committee of the American Student Health Association was formed in 1931 following the first National Conference on College Hygiene at Syracuse University. At that time six institutions of higher education were known to have begun tuberculosis programs—the state universities of Minnesota, Michigan and Pennsylvania, Western Reserve University, Vassar and Yale. At the close of the first five years of the Committee's work, fifty colleges reported programs. Now, at the end of the second five years, three hundred and four institutions so report. This number represents every section of the country, and includes endowed colleges and universities, state colleges, institutes, teachers' colleges and universities, and civic colleges and universities. State universities made the best showing; the small, privately endowed colleges the least satisfactory.

In 1936-37 there were ninety-one colleges using the tuberculin test on 56,224 students; in 1940-41, two hundred and fifty-five colleges were doing so, and the number of students taking the test had increased to 149,744. The percentage of institutions using the Mantoux method dropped in this period from 88 to 82. Recent experiments in some localities with patch testing, along with some schools using the Pirquet method because the state supplies only that type of testing material, account for the drop.

The number of colleges using routine chest films without prior tuberculin testing increased from 12 per cent in 1936-37 to 16 per cent in 1940-41. A few colleges and universities have adopted miniature-film mass surveys.

There has been an encouraging increase in the number of colleges examining nonstudent personnel. In 1936-37, thirty colleges required the examination of food handlers, and twenty-nine the examination of the faculty and administrative employees, while in 1940-41 there were one hundred and eight colleges reporting the examination of food handlers and ninety-two the examination of the faculty and administrative personnel.

The annual reports of the Tuberculosis Committee have disclosed a startling difference in the amount of tuberculosis in students discovered in colleges with case-finding facilities and in schools with no program of case finding. In the second five-year period, 1936-41, the colleges in the latter category reported the discovery of 184 new cases of tuberculosis among a student enrollment of

668,895, a rate of 27.5 per 100,000. The colleges with case-finding facilities reported the discovery of 3523 new cases in a student enrollment of 1,850,755, a rate of 190.5 per 100,000, during the same period.

Roughly, this confers a ratio of 7:1 in favor of the progressive colleges dedicated to the proposition that tuberculosis must be tracked down to its lair, found early and treated promptly, if it is to be defeated ultimately in the individual and in the Nation. These figures imply that thousands of cases of tuberculosis, many of them infectious, are being harbored and ignored among American college students through utter failure of most colleges to comprehend that a threat to health truly exists and that a major social and economic problem clamors for action.

Letters from college administrators attempting to justify the nonexistence of case-finding programs in their respective institutions indicate the prevalence of such ancient ideas as, that only when "consumption" arrives is tuberculosis present, that early tuberculosis can be ruled out by a physician's cursory certification or by stethoscopic search, or by stratified social selection. The survival of these fallacies among educated people represents our failure to carry the truth ceaselessly and convincingly to every person whose information, no matter how complete in most directions, remains barren with respect to tuberculosis.

The war, which in its train brings conditions of overcrowding and overwork, the disruption of public and private medical services, the curtailment of budgets and the restriction of personnel, gives opportunity also for the increase of tuberculosis unless special efforts are made to guard against this menace. Army, Navy, industry, public health—all must fight together and against tuberculosis, but it is of the very essence and function of education that colleges and universities lead the battle.

It is suggested that just as counties were once accredited for eliminating tuberculosis from their dairy herds, even as today they are being accredited in Minnesota for driving death rates and infection rates to low levels, colleges and universities might be accredited by the American Student Health and the National Tuberculosis associations, once they have inaugurated and maintained acceptably a modern program against student tuberculosis. Laggard colleges might thus be tempted to make the necessary adjustments so that they could be listed on the Roll of Honor of progressive, public-spirited institutions.

The war must go on. The war must be won, and we must win it, both from our external foes and from such borers-from-within as tuberculosis. —Reprinted from *Tuberculosis Abstracts* (December, 1942).

BOOK REVIEW

War Department. Technical Manual TM 8-240. Roentgenographic technicians. 8°, paper, 223 pp., with 109 illustrations. Washington, D. C.: Government Printing Office, 1941. 35 cents.

This manual contains about 70 pages of descriptive material and a series of reproductions to show the position of the patient and the resulting radiograph. The descriptive material includes several chapters on the physics of magnetism and electricity, as well as chapters on the operation of an x-ray machine. The material as presented is in general correct, although there are a number of minor errors that might easily have been corrected had the manuscript been submitted to a physicist before printing.

NUMBER 26

TREATMENT OF ARTHRITIC CONTRACTURES OF THE KNEE

JOHN G. KUHN, M.D.*

BOSTON

DEFORMITIES at the knee are among the commonest and most disabling conditions in chronic arthritis, occurring next in frequency to deformities of the hands and feet. Five hundred and eighty-six contractures at the knee (in 313 patients) were found in 1453 patients suffering from chronic arthritis on the wards of the Robert B. Brigham Hospital. A contracture is defined as a relatively fixed shortening of a group of muscles and their ligaments. This shortening develops rapidly within a few weeks. After it has been present for several years, it often leads to irreversible changes in the muscles. The relative frequency of the various types of contractures is given in Table 1. Most of these deformities were

of the tibia on the femur and external rotation of the tibia on the femur. Subluxation of the tibia

FIGURE 1 Flexion Contracture of 20° (the usual type of deformity)

TABLE 1. Classification of Types of Deformity in 313 Arthritic Patients

DEFORMITY	NO OF CASES	PER CENT
Flexion (more than 10°)		
Simple	504	80.5
With ankylosis of tibia and femur	32	5.1
With subluxation of tibia	19	3.0
With external rotation of tibia	7	1.1
Extension (10° or less of flexion)		
Simple	17	2.8
With ankylosis of tibia and femur	7	1.1
With knees showing no contracture	40	6.4
Total	627	

simple flexion contractures, since this is the usual position that the knee assumes when an inflammation is present¹ (Fig. 1). Flexion contractures of less than 10° were not included in this study because, so far as could be observed, little disturbance in function resulted from such a mild deformity at the knee joint.

Eighty per cent of the cases were uncomplicated flexion contractures. Secondary deformities complicating the flexion contractures were found much less frequently. These, in the order of frequency, were ankylosis of the tibia and femur, subluxation

occurred only with partial disintegration of the joint surfaces² and with the absence of protection at the back of the knee joint (Fig. 2). External

FIGURE 2 X-ray Photograph Showing Subluxation of the Tibia on the Femur.

rotation was usually associated with valgus of the foot and with prolonged muscular spasm in the biceps femoris muscle. Ankylosis of the femur

*Chief of Surgical and Orthopedic staffs, Robert B. Brigham Hospital.

and tibia was often the end stage of the arthritis process.³

Extension contractures occurred in 2.8 per cent of the knees. These were recorded only if the knee could not be flexed more than 10° from the fully extended position (Fig. 3). This type of contrac-

FIGURE 3. Extension Contracture of Both Knees (about 5° of motion in the right knee, none in the left).

ture was observed only when the knee was kept in extension for long periods during the active stage of the disease,⁴ or when much force had been used in the correction of a previous flexion deformity.⁵ In 7 cases, the extension contracture was complicated by ankylosis of the tibia and femur.⁶

Involvement of the knee by atrophic arthritis caused all the contractures except 11, which occurred as the result of hypertrophic arthritis. Usually, both knees were similarly involved in the same patient. But there were 40 patients with flexion contracture in one knee and no deformity in the other. The case histories of these patients suggested that local trauma played the major part in this involvement of one knee only.

The deformities that disturbed function to the greatest extent were flexion contractures of more than 30°. Symptoms of sprain soon appeared not only at the knee but also at the hip and foot. Subluxation and external rotation usually increased the symptoms. With flexion contractures of less than 20°, function at the knee was not always disturbed, but weight bearing on these flexed knees tended to increase the deformity. Minimal contractures (less than 10° of flexion) rarely led to significant symptoms unless there was much bony proliferation about the margins of the knee joint. In the mildest contractures, the deformity usually did not change if the arthritis was quiescent.

When the range of motion was greatly restricted in both flexion and extension, or when an ankylosis was present, there was little evidence of sprain at the knee; however, it was usually found in the low back and hip, less commonly at the foot and ankle. Extension contractures rarely produced a strain at the knee, since weight was borne with

the knee almost fully straight. But walking led to ache at the hip and ankle because excessive motion was demanded at these joints. Extension deformities were particularly disabling if the patient's work required much flexion of the knee.

To prevent and to correct these contractures of the knee, a program of treatment was evolved that has been modified as more effective methods have been found. In patients seen during the first six months of the arthritis, contractures could usually

TABLE 2. Program of Treatment of Contractures.

TREATMENT	INDICATION
<i>Prevention of Contractures</i>	
Avoidance of weight bearing	Pain on walking and articular inflammation
Splinting in full extension	Muscular spasm with tendency to flexion
Exercises	Weakness of muscles
<i>Correction of Flexion Contractures</i>	
Series of plaster casts	Contractures not corrected passively
Pad behind upper end of tibia	Early subluxation
Internal rotation of lower leg in plaster cast	Internal rotation of tibia
Caliper when standing	Knee too weak to maintain extension on standing
Exercises	Weakness of muscles with no pain on motion
Manipulation	Adhesions limiting motion in one direction only with no inflammation
Posterior capsuloplasty	Resistant flexion contracture with little destruction of articular surfaces
Traction (skeletal)	Flexion or subluxation after operation
Osteotomy	Knee fixed in bad position for weight bearing
Arthroplasty	Stiff joint
<i>Correction of Extension Contractures</i>	
Plaster casts in flexion	Fixation of knee in extension
Lengthening of quadriceps tendon	Resistant extension contractures

be prevented. Unfortunately, most of the patients came for treatment only after contractures had developed. The program of treatment and the usual indications are given in Table 2.

The most effective method of preventing contractures at the knee when arthritis was present was rest in full extension until the muscular spasm and pain had subsided. Walking was permitted when motion and weight bearing did not lead to pain. If the period of rest was prolonged beyond two weeks, exercises were often necessary to maintain strength and control of the muscles about the knee. Splinting of the knee in extension was required if there was a persistent tendency to flexion. Fixation was not continued longer than one week without examination of the knee and allowance of a little motion temporarily. Long fixation of the knee without motion tended to produce extensive muscular atrophy and a contracture in extension.

When a flexion contracture could not be corrected passively, an attempt was made to correct

it by a series of plaster casts (Fig. 4). With the fixation of a plaster cast, the muscular spasm usually subsided, and the knee could then be brought into more extension. After two days the plaster

effective method of correction in the resistant contractures was a posterior capsuloplasty, an operation in which the contracted posterior muscles and ligaments are lengthened.⁹ When there was much

FIGURE 4 *Gradual Correction of Flexion Deformity by Plaster Casts*

cast was cut into an anterior and a posterior half and was removed for short periods to permit the application of heat and for exercises when these could be performed without pain. When 10° or more of correction in the contracture had been obtained, a new cast was applied. Contractures were usually corrected by this method in from one to three months.⁷ For persisting weakness of the muscles of the thigh, a caliper was worn when the patient was walking, to maintain correction until the muscles became stronger.

When contractures did not show correction after the use of a plaster cast for several weeks, a manipulation was considered⁸ if motion was restricted in one direction only and if there was no evidence of inflammation in the joint. Usually, the most

destruction of the articular surfaces and motion was greatly restricted, an osteotomy¹⁰ usually led to a better functional result, with less pain on weight bearing, than a posterior capsuloplasty. Skeletal traction was used only after an operative procedure such as posterior capsuloplasty, particularly for the correction of subluxation of the tibia on the femur.

When there was complete destruction of the articular surfaces, with little or no motion in the joint, an arthroplasty¹¹—an operative attempt to form a new joint—was considered if the disease was inactive. Usually, this operation was performed on one knee only, since a certain amount of stability was always lost in the attempt to secure motion. More difficulty was encountered in the cor-

rection of extension contractures than in the treatment of flexion contractures. In the absence of ankylosis, an attempt was made to secure greater motion in flexion by a series of plaster casts holding the knee in flexion. Exercises and the pull of

The poor results shown by 23 per cent were due chiefly to failure to maintain correction after the operation was performed. In recent years, full correction of the contracture after the operation has been maintained by skeletal traction or by a plas-

TABLE 3. Results of Treatment of Flexion and Extension Contractures.

TREATMENT	TOTAL NO OF CASES	GOOD RESULT		FAIR RESULT		POOR RESULT	
		NO OF CASES	PER CENT	NO OF CASES	PER CENT	NO OF CASES	PER CENT
<i>Flexion Contractures</i>

Lengthening of quadriceps	1	0	—	1	100	0	—
Arthroplasty	1	0	—	1	100	0	—

gravity were also employed. When these procedures proved ineffective, a plastic lengthening of the quadriceps tendon¹² was considered.

The types of treatment used and the end results are presented in Table 3. The results of treatment are listed as good with a final result of less than 5° of contracture; fair with from 5 to 15° of contracture remaining; and poor when there was more than 15° of persisting contracture. In flexion contractures, a series of plaster casts was most frequently used. Much better results would have been shown if the contractures had been selected primarily for this treatment. Plaster casts were used in the early treatment of almost all patients. Of the 173 contractures not corrected by plaster casts, 42 were of more than ten years' duration, and 55 had been present over five years. Most of the contractures of long duration and of severe degree required surgical correction later. There is no satisfactory method of determining the resistance of contractures at the first examination. One can usually tell whether plaster casts will be effective only after several weeks of trial. Exercises alone, which were used only for the mildest flexion contractures or as palliative measures, relieved the deformity only when it was of short duration and slight degree. In most cases, exercise failed to prevent an increase in the deformity. It is not considered an effective form of therapy for arthritic contractures, and should be used only in combination with some form of support to the knee.

Posterior capsuloplasty resulted in full correction of the flexion deformity in 40 per cent of the cases.

ter cast. Skeletal traction after the manner of Russell¹³ was particularly helpful in the correction of severe subluxations of the tibia.

When the patella was bound to the femur by adhesions or by ankylosis, it was necessary to free it to permit full contraction of the rectus femoris muscle (Fig. 5). In three posterior capsuloplasties,

FIGURE 5. Ankylosis of Patella to Femur

the patella was removed, and in three others it was loosened from the femur and then covered with fascia lata. About equally good results were obtained with these methods. No correction of a flexion deformity was maintained when the patella remained fixed to the femur.

The results of manipulation were disappointing. No deformity was fully corrected, and only 36 per

cent were improved. In 4 cases ankylosis in extension occurred after manipulation and in 4 others fracture of the femur occurred during manipulation. Manipulation should be reserved for the correction of contractures of short duration, with limitation of motion in one direction only, in the presence of inactive disease and with no great atrophy of bone or muscle. The only advantage of manipulation is that in selected cases it may release adhesions that cannot be corrected by plaster casts alone.

Arthroplasty for the relief of bony ankylosis at the knee was performed in 20 cases. The poorest results were observed when a great amount of flexion was present before arthroplasty. In such cases, skeletal traction or a series of plaster casts was used to correct the flexion after operation. Arthroplasty was far less effective in chronic arthritis than in ankylosis after trauma or acute infections.

Traction was not an effective method of correcting flexion contractures. Improvement was obtained in only a third of the cases in which it was used. Even skeletal traction was too painful in contractures of long duration to be effective, beneficial results were obtained only after operative procedures in which the contracted muscles and ligaments had been released.

Synovectomy¹⁴ was not used to correct a contracture primarily. At times, it aided the correction of deformity by permitting increased motion at the knee. This operation, planned for the removal of inflamed and thickened tissue from the knee joint, sometimes led to an increased range of motion when motion was hindered by the thickened tissue.

Wedging casts and forceful stretching of the knee with special apparatus were not effective in arthritic contractures. Although correction sometimes resulted in the less resistant contractures, greater stiffness of the knee joint usually followed. In the resistant contractures, pressure sores often developed before much if any correction was obtained.

Osteotomy, a procedure rarely used, led to an improved position for function. This method resulted in no increased motion but gave a better position for weight bearing. Osteotomy, rather than posterior capsuloplasty, was employed when there was little motion in the joint and extensive destruction of the articular surfaces. Usually, in arthroplasty was the operation of choice.

Arthrodesis,¹⁵ although it prevented deformity by eliminating motion at the knee, was not a popular procedure. Only one such operation was performed. Four other patients who had an arthrodesis performed on the knee joint before coming

to the hospital stated that they preferred a painful, movable knee to a stiff, painless one. It is a justifiable treatment in chronic arthritis only when there is marked destruction of the joint, with persistent pain on weight bearing, in a patient who must stand at his work.

The treatment of extension contractures has not been encouraging. The results were considered good if the knee could be flexed 60° from full extension, fair if the knee could be flexed 45° to 60° and poor if there was less than 45° flexion. With less than 45°, the patient was unable to climb stairs normally, or to use the leg in rising from a seat. Casts rarely led to an improvement of an extension contracture. Gravity and exercises would be expected to lead to increased flexion, but these were also relatively ineffective. A plastic lengthening of the quadriceps tendon seemed to be the most effective treatment for extension contractures of long duration.

CONCLUSIONS

Arthritic contractures at the knee can be prevented by rest, if weight bearing causes pain, by splinting of the knee in full extension, if there is muscular spasm, and by exercise, if there is muscular weakness and atrophy.

When flexion contractures cannot be corrected passively, the best early method of correction is a series of plaster casts, each cast securing as much extension as possible. Calipers and exercises are usually required to maintain full correction until muscular strength is regained.

Flexion contractures too resistant for plaster casts are corrected most easily by a posterior capsuloplasty, which leads to painless weight bearing if the articular surfaces are not destroyed. Manipulation, wedging casts and traction are relatively ineffective procedures. Skeletal traction is of value only after operations that free the contracture and permit extension gradually or after the correction of a subluxation.

Arthroplasty is the procedure of choice in ankylosis if motion is desired, but not in chronic arthritis. Osteotomy is employed when a better position for weight bearing alone is desired.

Plastic lengthening of the quadriceps tendon seems to be the most effective treatment for extension deformities, in general, the treatment of such contractures is not encouraging.

IMPORTANT CLUES IN CARDIOVASCULAR DIAGNOSIS*

PAUL D. WHITE, M.D.†

BOSTON

IT IS of great value in the practice of medicine to keep clearly in mind certain simple diagnostic rules and diligently to seek various important clues to diagnosis. This is particularly true in the study of patients with cardiovascular symptoms or signs. A complete and accurate cardiovascular diagnosis can often be made by the realization of the significance of a single symptom or sign or by a single well-placed question. It is of special interest also that the very multiplicity of symptoms in a nervous person is encouraging evidence of a large nervous as contrasted to an organic cardiac responsibility for illness. The more symptoms, often the less disease.

SYMPTOMS

Pain. Substernal tightness, not often dignified as pain at first, beginning on effort after breakfast on a cold morning in the fall, usually mild the first week or two, and occurring in a business or professional man in the fifties, is, in my experience, the commonest type of onset of angina pectoris due to coronary heart disease. Usually, angina pectoris is a pressure sensation, which is often described by the patient as a difficulty in breathing, and sometimes, therefore, gives rise to an erroneous diagnosis of dyspnea from some cause or other. The patient may say that it is not pain to him, but neither is it true breathlessness. Thus it is important to analyze this symptom in detail. The physician should not use the word "pain" alone in his questioning.

Angina pectoris is often mild, especially at its onset. It does not need to be severe; it may be merely a sensation of slight pressure on some effort that would not normally bring it on. The amount of exercise is more important than the amount of pain. The presence of even mild substernal discomfort on effort is more important than the severity of the pain. The severity of the discomfort or pain is largely dependent on the sensi-

tivity of the person. A sensitive, nervous person will feel the pain more acutely. If slow walking alone brings on mild oppression, this is much more significant than if the pain, no matter how severe, is produced by a faster gait.

Angina pectoris almost invariably occurs at first on effort. If it comes at rest (angina decubitus) one is dealing with an acute coronary occlusion, with or without myocardial infarction. Or else there is some other cause for the pain, perhaps a gastric condition (cardiospasm) or some responsible lesion in the chest other than heart disease.

Meals predispose to angina pectoris on effort, especially breakfast. The patient tends, during the day, to get his second wind, as one might say, and is able to do things after supper or lunch more readily than after breakfast.

Often a patient does not speak of this symptom for days or weeks after it first appears; maybe he does not mention it for years. I have found that especially characteristic of physicians.

The pain tends to be a waxing pain. When the person affected walks a little faster or uphill, the pain grows more and more severe. As a rule, it is a continuous pain until the person stops—continuous, but lasting only a few minutes. It is not a throbbing pain; it is not a sharp pain; it is not a stab; it is not a prolonged ache.

The commonest age at which angina pectoris first appears is the fifties; fifty-two or fifty-three is the average of such patients whom I have seen in the last twenty years. They range, however, from the thirties up to the eighties, but most of them are still active in their work long before retirement. Business or professional men are especially affected; business and professional women may have such symptoms too, but much less commonly. Housewives appear to have angina pectoris less frequently than do business and professional women.

The one most striking etiologic relation of angina pectoris is that of sex. It is preponderantly

*Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 12, 1942.

†Lecturer in medicine, Harvard Medical School; physician, Massachusetts General Hospital.

a man's disease. It is essential to remember that women under fifty rarely suffer from true angina pectoris or other manifestations of coronary heart disease, which in the earlier years of life is, as just stated, largely confined to men. The few younger women who do develop it almost always have either hypertension or diabetes mellitus, or else there is a strongly suggestive family history. Those women who have a family history of angina pectoris or coronary heart disease in both branches of the family or in their maternal ancestors alone at young ages, have a tendency to angina pectoris under fifty, even without hypertension; however, this is rare. If a woman is under fifty, chest pain is probably not evidence of heart disease.

Substernal discomfort coming on when seated or recumbent but not on effort is not due to coronary insufficiency; it is most likely of gastric origin, and due to cardiospasm, quite possibly secondary to gastritis from an hiatus hernia. It is vital to distinguish angina pectoris from the heartache over the left breast which is commonly found in other conditions, especially indigestion and nervousness. Tenderness on pressure or palpation over the precordium decreases very much the clinical significance of heart pain, which usually turns out to be only the heartache of neurocirculatory asthenia or pectoral muscle strain.

Another vital point is this: in the presence of prolonged precordial pain, with or without a pericardial friction rub, a definite exacerbation of the pain on deep breathing means acute pleuropericarditis and not coronary thrombosis with myocardial infarction. Misinterpretation in such cases has probably caused frequent errors in diagnosis. Thus, one of the most valuable test questions of all concerns the effect of deep breathing. If in a patient with precordial pain a deep breath increases the pain or perhaps is the chief cause of it, a diagnosis of pleuropericarditis is indicated. The change in the electrocardiogram is atypical and often transient. Cardiologists are now beginning to separate from the large number of patients diagnosed as having coronary thrombosis certain exceptions like the foregoing, with various conditions that may simulate coronary heart disease.

An accurate history will almost invariably enable one to establish the correct cardiac diagnosis. The history is the essential part of the differential diagnosis of heart disease. As already stated pain that comes on when seated or recumbent but not on effort is most likely of gastric origin, and perhaps due to an hiatus hernia. Such pain is often actually improved by standing and walking about; the stomach settles away from the hernia, and there tends to be relief. Belladonna may also give relief,

as well as a change in diet, with frequent small meals. One can, of course, have both conditions,—that is, angina pectoris and cardiospasm,—and not uncommonly one may excite the other. It is important to recognize this fact. Many patients with angina pectoris experience relief after belching, but the belching and the cardiospasm associated with it are secondarily induced by the attack of angina, or vice versa. The presence of both conditions adds to the difficulty of the diagnosis, but also to its interest.

Excessively severe chest pain occurring abruptly,—that is, within two or three seconds,—maximum at onset and radiating down the back, in a hypertensive person of middle age or older should suggest dissection of the aortic wall, that is, a dissecting aortic aneurysm. From the coronary-thrombosis group a few patients, as a rule hypertensives, can be picked whose aortic wall has split, usually along the whole length of the aorta and down into the iliaes.

The last point concerning pain has reference to right-upper-quadrant discomfort on effort, due to acute engorgement of the liver, in a patient with mitral stenosis or other cause of right-ventricular strain; this should be viewed with suspicion as an early, probably the earliest, symptom of failure of the right ventricle. Yet, even today, most doctors think of shortness of breath as being the first evidence of heart failure, even in the presence of mitral stenosis. Strictly, this is not true. To be sure, there is a defective mechanism whereby the increased shortness of breath, due to the pulmonary vascular congestion from mitral stenosis, may antedate actual failure. Mitral stenosis acts as a mechanical bar. With tachycardia due to effort, or coming paroxysmally, as in some cases of auricular fibrillation, the right ventricle pumps too much blood into the lungs; this causes congestion of the lungs and shortness of breath. Such dyspnea is due to overaction of the heart, not to heart-muscle failure.

The first symptomatic evidence of right-ventricular failure arises from engorgement of the liver. Naturally, just as the lungs fill up with blood when the left ventricle fails, with dyspnea as the first symptom, so swelling of the liver, with pain, is evidence of failure of the right ventricle. This may come on effort, just as shortness of breath may come on effort, but it is not as yet well recognized. Occasionally this clue is useful. Generally by the time right-heart failure is established, enlargement of the liver has become chronic and no longer painful, but the beginning of the congestion of the liver is painful. This symptom is worth looking for in patients with mitral stenosis who complain of

heaviness or discomfort, especially on effort, in the right upper quadrant of the abdomen. The liver can soak up blood rapidly, and it can also shrink extremely rapidly. I have seen enormous livers subside in forty-eight hours after the beginning of treatment. Thus failure of the right ventricle with a congested liver, like failure of the left ventricle with congested lungs, may subside quickly.

Dyspnea. When the heart is normal in size, dyspnea is not due to heart disease, that is, to either congestive failure of the left ventricle or mitral stenosis,—but most commonly to pulmonary disease or bronchial asthma. When such patients complain of dyspnea, digitalis should not be given. Hence it is extremely important in doubtful cases to determine the size of the heart. When it is normal, dyspnea must be related to other factors. There may be occasional exceptions,—cases of angina with asthmatic reflex,—but they are so rare that they seem to “prove the rule.”

In the presence of chronic hypertension of considerable degree, or myocardial infarction, new or old, or aortic valve disease, paroxysmal dyspnea, especially at night, is a bad sign, unless there is paroxysmal tachycardia, auricular fibrillation or severe pulmonary infection or infarction to set it off. It is evidence of acute failure (dilatation) of the left ventricle. Paroxysmal dyspnea has a much better prognosis in mitral stenosis. As stated previously, in mitral stenosis congestion of the lungs is not a sign of muscle failure; it is mechanical. I now have under my care a patient with mitral stenosis who ten years ago nearly succumbed to acute pulmonary edema caused by paroxysmal auricular fibrillation. She developed permanent auricular fibrillation and the heart rate has held ever since at about 70 under digitalis. The patient does not now have dyspnea, and remains in a fair state of health, an impossibility had she had left-ventricular failure as a cause of her pulmonary edema ten years ago. Cheyne-Stokes respiration in a patient when awake means serious circulatory failure. On the other hand, sighing respiration, like precordial tenderness, is a good sign, so far as the heart is concerned. If a patient heaves a deep sigh and says, “Well, here I am at last, Doctor,” one knows at once that the diagnosis is chiefly nervous fatigue, and can give, as a rule, a favorable prognosis. But a nervous person who sighs can also have angina pectoris, and nervous people can and do die of angina pectoris or coronary thrombosis.

Periodic dyspnea with tachycardia, collapse and fever, especially at rest, often means pulmonary embolism, particularly in a cardiac patient with congestive failure. This complication is impressive not only because of its importance and frequency,

but also because of its neglect. Many persons who are ill in a hospital or at home have unexplained attacks of dyspnea and prostration, and a slight elevation of temperature for a few days. Physical examination may fail to reveal pulmonary infarction, which is often hidden behind other signs; yet almost invariably embolism is responsible for such attacks.

It may be difficult to distinguish between paroxysmal tachycardia and pulmonary embolism. The pulse may go up to 150 or 160 in a few seconds or minutes. One suspects paroxysmal tachycardia, but then finds increased temperature, which is not caused by paroxysmal tachycardia or by heart failure alone—that is, when it amounts to more than half a degree or a degree. Therefore an elevation of two or three degrees of temperature for a few days after an unexplained attack of dyspnea or tachycardia is not to be attributed to either of these conditions. There is likely to be an infarction of the lungs. The embolus comes almost invariably from the legs. One often blames the heart, but in these cardiac cases especially there is a stagnation of blood in the veins of the legs. There may be no sign of phlebitis on physical examination in a good many cases. I have seen three or four of these patients with apparently perfectly normal legs but with proved thrombophlebitis (better called “phlebothrombosis”). There may be an incomplete block of one of the long veins, especially the superficial femoral or long saphenous, which is responsible for the pulmonary embolism that is causing the symptoms. One should be everlastingly on his guard against this complication. It may occur in a person who has never had heart disease. It is to be expected after an injury or an operation, but it is a common medical complaint as well.

One should in such cases always inquire as to possible injury. A recent patient, an elderly man, was suffering a second attack of so-called “pneumonia,” which was really a second pulmonary embolism. There had been no operation, and no swelling of the legs was present on examination. On inquiry, it developed that before the first attack of “pneumonia,” he was thrown across the room while wrestling, injuring his leg; he had had a temporary swelling of the ankle. Ten days later he had the second attack; the leg was responsible for the pulmonary embolism. Therefore inquiry should always be made as to possible injuries. One can save lives by ligating the responsible veins, when one is quite sure they are responsible. X-ray diodrast venograms, which are now possible, must be taken correctly. Not only is the technic important, but they must be interpreted accurately. Under such conditions they may reveal the correct cause of pulmonary embolism, which may have

been wrongly blamed on the heart. In that event one can tie off the veins on both sides. Lives can be saved by this procedure even more than by giving anticoagulants (such as heparin) after the phlebothrombosis has begun.

Palpitation. Palpitation as a preponderant or isolated symptom generally means an irritable or nervous heart, without structural disease. There need be no serious pain or dyspnea, but a good many nervous persons have every symptom, palpitation, shortness of breath, heartache, fatigue and faintness. The more symptoms, the less significant any one of them is when considered per se. Rarely palpitation does mean heart disease. The majority of long-lived persons throughout the world probably have occasional extrasystoles, of which they may or may not be conscious. Even auricular fibrillation may occur as a minor and isolated functional disorder. In over 100 cases I have seen auricular fibrillation as a relatively unimportant disorder with no other evidence of heart trouble; the hearts of these patients appeared to be structurally sound and essentially normal.

Premature beats, paroxysmal tachycardia and auricular fibrillation and flutter are the arrhythmias that are commonly the cause of palpitation, but still more commonly palpitation is merely an uncomfortable normal rhythm, fast, slow or average in rate.

Tachycardia in abnormal rhythms may explain pain without effort in coronary heart disease, congestive failure in cardiac strain and enlargement from any cause, even in normal infants, dyspnea in mitral stenosis from mechanical blocking of the pulmonary vessels with extra blood, and psychoneurosis, mild or severe, in patients who may become conditioned to any tachycardia. Arrhythmia and tachycardia may simulate coronary insufficiency. When an attack occurs at night, it is important to see the patient during it, or to get an accurate history of the attack. Tachycardia, which is difficult to control by digitalis and rest, particularly in auricular fibrillation, strongly suggests excessive nervousness, thyrotoxicosis, infection or infarction, especially of the lungs. If the heart cannot be adequately controlled in a cardiac patient one of these conditions is indicated.

Faintness and syncope are of more significance alone than when attended by other cardiac symptoms. If a patient faints and has other symptoms, such as palpitation and shortness of breath, neurocirculatory asthenia is the probable explanation.

SIGNS

With finger-clubbing, cyanosis means serious congenital heart disease, or severe chronic pulmonary disease, or is the result of prolonged residence

at altitudes of fifteen thousand feet or more. Cyanosis of high degree is rarely seen in congestive heart failure per se, and so when it appears in such cases, it should suggest a probable complication of pulmonary infarction or infection. Ayerza's disease (that occurring in so-called "black cardiacs") is more a pulmonary than a cardiac disease. The heart may be secondarily affected, with a large right ventricle, but failure of such hearts is seldom seen. The deep cyanosis in such cases is due primarily to the pulmonary disease. Cyanosis should be distinguished from argyria and polycythemia vera. The former occurs predominantly in the cheeks, tongue, ears and nose. Argyria occurs around the eyes and the sides of the nose and mouth. In a congenital cardiac patient, exercise increases the cyanosis, but in argyria it brings out a pinkness that tends to conceal the slate-blue tinge of the skin. Polycythemia gives a deep-red, rather than a purple color.

Jaundice in congestive failure suggests a large lung infarct superimposed on congestion of the liver, which is unable to take care of the blood pigment taken up from the pulmonary infarct.

Cardiac enlargement almost always means permanent heart disease, but there are a few exceptions, with acute and reversible dilatation, as in acute cor pulmonale, acute rheumatic myocarditis, excessive paroxysmal tachycardia, myxedema and some cases of myocardial infarction. One can distinguish preponderant left-ventricular and right-ventricular enlargement best by electrocardiograms, but total enlargement is best detected by x-ray study. A precordial bulge may be due to marked enlargement of the right ventricle.

As to sounds and murmurs, a greatly accentuated pulmonary second sound, especially one greater than the aortic sound, in hypertension means left-ventricular failure. In young persons without murmurs, it usually means congenital auricular septal defect or cor pulmonale; it is the rule in marked mitral stenosis. It is important to listen to the heart sounds. I attended medical school at a time when murmurs were all the rage and not much attention was paid to heart sounds. It was not realized that heart sounds were more significant than murmurs.

Gallop rhythm is almost always a sign of serious dilatation of the ventricles. One should, however, always rule out heart block.

Delicate aortic and mitral diastolic murmurs vary in audibility with body position, the type of stethoscopic chest piece and exercise. They are too often missed. In the interpretation of a continuous murmur, a venous hum in or transmitted from the neck should be ruled out; when that is done, such a murmur over the pulmonary-

valve area is the sign par excellence of patency of the ductus arteriosus.

A harsh systolic murmur at the apex, heard also at the aortic area but not over the lung bases, usually means aortic stenosis; when more blowing in character and heard also at the lung bases but not in the aortic area, a systolic murmur means mitral regurgitation. A systolic thrill palpable over the aortic valve area almost always means aortic stenosis, rarely an aneurysm; at the left border of the sternum it means as a rule a congenital ventricular septal defect.

Left versus right hydrothorax in heart disease is more often due to pulmonary infarction or pleurisy than to congestive heart failure. When hydrothorax is limited to the left side, it is due to some condition other than heart failure, unless the right pleural cavity is obliterated, because fluid usually collects earlier, and more frequently and more copiously in the right pleural cavity than in the left. If you find a limited hydrothorax on the left side, look out for pleurisy, pulmonary infarction or obliteration of the pleura on the right side. Also, look out for polyserositis. All fluid collections are not due to dropsy. There may be inflammation of the type of a polyserositis.

The same statement applies to the finding of rales at the lung bases; that is, pulmonary infection or infarction is the commonest cause of basal lung rales, or even atelectasis may be the cause, and not congestive heart failure.

Engorged neck veins almost always mean right-heart failure, rarely acute or chronic constrictive pericarditis or pressure from a mediastinal tumor, and they practically always mean that the liver is enlarged.

Enlargement of the liver without dilated neck veins and increased venous pressure indicates a noncardiac cause, such as cirrhosis in the early stage, hepatitis or tumor. The position of the liver edge is an unreliable indication of the size of the liver.

Exclusive or preponderant unilateral leg edema means local disease, even in heart failure, provided the effect of gravity—that is, of lying on one side—is ruled out. Often this disease is phlebothrombosis, which may lead to pulmonary embolism.

As to the pulse, a great difference in volume of wrist pulses suggests aortic aneurysm, but pressure from a cervical rib or a tight scalenus anticus muscle on one or the other subclavian artery may be responsible. A well-marked pulsus paradoxus favors acute or chronic constrictive pericarditis, but compression of subclavian arteries on raising the shoulders in deep inspiration should first be excluded. True pulsus alternans means serious left-ventricular weakness, except in cases of excessive paroxysmal tachycardia. Absence of pulse in the feet points oftenest to local occlusive arterial disease or embolism, dissecting aortic aneurysm or coarctation of the aorta. The deep systolic jugular pulse must not be confused with the carotid pulse. It should be recognized that there is a wide range of normal pulse rates in man.

* * *

In conclusion the examiner must everlastingly use his eyes and fingers, his ears and his brain in searching for these simple but important cardiovascular diagnostic clues; in fact, if he is on his toes, he may introduce some new and useful clues himself.

THE USE OF ETHER IN OIL INTRAMUSCULARLY IN THE TREATMENT OF BRONCHIAL ASTHMA

ANGELO L. MAIETTA, M.D.*

WINCHESTER, MASSACHUSETTS

OLIVER WENDELL HOLMES spoke of his asthma as "the slight ailment that promotes longevity." Unfortunately, however, not all cases of bronchial asthma can be so described. Many cases are characterized by acute symptoms which, though severe, are not prolonged. In others, the asthmatic symptoms not infrequently become chronic and, with the passage of time, not only more intractable but also more severe. Quite often, during an acute episode, some patients pass into a more or less refractory stage during which their symptoms, despite energetic treatment, remain for a variable period constantly acute and relatively uninfluenced.

In the severely acute form, in intractable bronchial asthma (with or without acute seizure) and in status asthmaticus, I have found that the administration of ether in oil intramuscularly has produced gratifying results within a comparatively short time. I have successfully employed this preparation as an adjuvant form of palliative therapy in conjunction with other well-recognized and accepted methods. Its action has always been beneficial.

A report of the results obtained by treating 11 cases of bronchial asthma with intramuscular injections of ether in oil is herein presented. I fully appreciate that although ether in oil intramuscularly as an adjuvant appears to influence beneficially the asthmatic state of this small group of patients, much more clinical investigation is required for a more comprehensive evaluation of its effect.

MATERIAL

Ether in oil[†] can be obtained commercially in hermetically sealed ampules each containing 2 cc. of a sterile solution of equal parts, by volume, of anesthesia ether and peanut oil.

The administration of ether by injection is neither new nor rare. For years, ether has been classified as a diffusible stimulant¹ and recommended as a hypodermic medicament in its unadulterated state in doses of 15 to 20 minims, repeated in fifteen minutes if necessary.

In 1914, Audrain,² in France, introduced the intramuscular injection of ether as an anticonvul-

sant for the treatment of whooping cough in doses of 1 to 2 cc., repeated daily if required. In 1924, Mason,³ employing the same technic, was one of the first to introduce this therapy in America. Although the symptoms were favorably influenced, many American investigators thought that the treatment with crude ether hypodermically was not desirable because in a considerable number of cases pain, abscess formation and necrosis developed at the site of the injection. This serious objection was later overcome by diluting the ether with a bland oil (peanut oil) and keeping it aseptic in hermetically sealed ampules. In 1929, Levy and Finkelstein⁴ reported the use of this sterile ether in oil solution in 104 cases of whooping cough in which more than six hundred injections were administered without the occurrence of abscess formation or necrosis. The dose employed was 1 cc. of ether in 1 cc. of peanut oil, repeated on alternate days or daily as required. This is the same preparation of ether in oil that I have used for the treatment of bronchial asthma.

APPARENT MODE OF ACTION

There is ample evidence that ether, in some manner not as yet fully understood, has a modifying pharmacologic action on the asthmatic symptoms. According to Rackemann,⁵ ether in experimental anaphylaxis modifies anaphylactic shock so that the animal survives a dose of antigen that would otherwise be fatal. Vaughan⁶ states that asthmatic patients often experience relief for variable periods following surgery. This fact is well recognized by many allergists. Ether anesthesia was deliberately induced by Kahn⁷ in 4 patients with intractable asthma. They were temporarily relieved, but not for so long as sometimes happens after surgery. Since its introduction by Maytum,⁸ ether in oil by rectum for the relief of severe asthma has been well received by a number of investigators.

These facts have led to the intramuscular administration of ether in oil as an adjuvant for the treatment of severe bronchial asthma. Despite the fact that this method has had a limited employment, the results are so constant that an apparent mode of action may be rationalized.

Although the ether is mixed with peanut oil, the latter does not prevent the immediate diffusion of the ether because patients can taste and smell it within a few seconds following its introduction

*Associate professor of medicine, Middlesex University School of Medicine, Waltham, Massachusetts, physician in-chief, Allergy Clinic, Middlesex Hospital, Cambridge, physician, Winchester Hospital, Winchester.

[†]Ether in oil is prepared by the Loeser Laboratory, Incorporated, New York City.

into the body. On the other hand, the oil does materially prolong its volatilization and absorption, because patients are able to taste and smell it for twelve to twenty-four hours. From this it appears that absorption of the ether begins immediately but, owing to the oil, is prolonged, and that excretion occurs principally by the lungs.

It is probably because of the slow absorption of such a small dose that a slight depressing effect is maintained on the central nervous system. This depressing effect acts as an anticonvulsant and sedative and appears to influence favorably the bronchospasm and the patient's apprehension.

Also, because of the slow excretion of the ether by the lungs, tenacious mucus apparently is loosened and dislodged from the mucous membrane of the bronchial tree. Expectoration thus is facilitated. It is the difficult expectoration of this mucus, whether present in small or large amounts, that produces much distress because, owing in part to its foreign-body action, patients cough violently in an attempt to remove it. By loosening the mucus, its expectoration is accomplished more easily and quickly and less energy (coughing) is expended to expel it.

METHOD OF ADMINISTRATION

Ether in oil should always be injected intramuscularly, preferably in the gluteal or deltoid regions. Strict antiseptic precautions should be observed at all times. Immediately prior to the injection, the skin should be prepared antiseptically. For the injection, a 22-gauge intramuscular needle should be employed. Although a larger one permits a faster introduction of the material, this enhances the risk of rupturing a small blood vessel deep in the muscle tissue, which would allow seepage into the blood stream. Obviously, for this reason also, the injection should be made slowly, and after insertion of the needle the piston should be withdrawn slightly to ascertain the position of the needlepoint. If it is in a blood vessel the needle should be withdrawn and reinserted.

EFFECT OF INJECTIONS

When ether in oil is injected intramuscularly, the effects on an asthmatic patient may be described as immediate and delayed. The immediate effects are fleeting, occur within a few seconds, quickly disappear and are relatively unimportant. The delayed action of the preparation is apparently extremely beneficial, is usually evident in about two hours and may last from several hours to a week or several months.

Immediate effects. Immediately following the intramuscular injection of ether in oil, the patient is able to taste and smell ether from his breath.

This occurs within a few seconds to about three minutes and continues for twelve to twenty-four hours. Patients state that it is not unpleasant.

As soon as the needle is withdrawn, or even while administering the injection, most patients complain of slight to moderate, but not distressing, pain at the site of the injection. It has been described as a sharp, stabbing, burning or piercing type of pain, which disappears within a few minutes. No asthmatic patient thus treated has refused an intramuscular injection of ether in oil because of the slight pain it had produced in the past. At no time was there induration, edema, necrosis or abscess formation at the site of and as the result of the injection.

Following its administration, there is a slight increase in the pulse rate, usually about ten beats per minute. Its character remains unaltered. As a rule, the systolic blood pressure is slightly elevated (5 to 15 mm. of mercury). Occasionally the blood pressure may remain stationary or may even drop (about 10 mm.). The changes in both the pulse rate and blood pressure are transient, lasting about twenty minutes. These changes are undoubtedly due to the stimulating action of the ether. The patients, however, have not complained of palpitation and have experienced no ill effects.

About fifteen minutes after the injection, some patients occasionally have a slight feeling of dizziness and coldness of the extremities, particularly of the feet. The sensations disappear quickly, usually within a few minutes, and cause no alarm. These symptoms, more correctly described as side effects, are probably due to the odor of the ether that the patient obtains either while the injection is being prepared or, following the injection, from the taste. This mild side reaction is encountered in only a very few patients. In those in whom it occurs, it is no longer evident after the third or fourth injection.

Delayed effects. The therapeutic effects following the intramuscular injection of ether in oil become evident in about two hours. They are apparently due to the anticonvulsant and expectorant actions of the ether. Patients become quieter and breathe more easily. The ether also appears to have a favorable action on the bronchospasm. In cases in which epinephrine produces either partial or no relief, it again becomes effective if administered in one to three hours following the ether injection. Further, expectoration of tenacious mucus becomes easier. Whether the patient has "dry" asthma, with small amounts of a glistening, pearly material, or "moist" asthma, with large amounts of a thick, mucoid, yellowish-green substance, both types of which are difficult to expect-

torate, ether, excreted through the lungs, seems to hasten and facilitate the clearing of this substance from the bronchial tree. The elimination of this mechanical factor (tenacious mucus) immeasurably aids in terminating the attack.

DOSE AND RESULTS

Acute bronchial asthma Of the three clinical groups considered here—acute bronchial asthma, chronic bronchial asthma and status asthmaticus—the first is the least important because, in an uncomplicated case, sooner or later the symptoms respond to the usual medications. However, there are patients who respond favorably but not completely and in whom palliative medication must be continued for several days until relief is obtained. In such cases, an intramuscular injection of ether in oil, repeated in four to six or twelve hours if necessary, appears not only to aid the symptoms but also to render epinephrine and ephedrine more efficacious. One or two injections are usually sufficient.

Six patients, having had an attack of acute asthma from two to five days, were thus treated. All of them responded fairly well but not satisfactorily to injections of epinephrine, 1/1000, and to a combination of 1/2 gr of ephedrine sulfate, 2 gr of aminophyllin and 1/4 gr of phenobarbital, given by mouth. Four of them received one intramuscular injection of ether in oil, the remaining 2 received two each. Within two hours, the asthmatic symptoms were rapidly controlled. The patients became quieter, were able to breathe more easily and expectorated more freely. Thereafter, the usual palliative medications effectively controlled the symptoms.

Chronic bronchial asthma Patients in this group have usually had their asthma for years, some as long as thirty or forty years. They generally have asthma the year around and suffer many acute exacerbations. Some of them have developed emphysema, with or without a barrel-shaped chest, and in some a minimal amount of tubular or sacular bronchiectasis is present. These patients are constantly raising a thick, mucoid or yellowish green substance. Its removal by coughing often produces much distress and aggravation of the symptoms.

In this group, ether in oil intramuscularly is extremely beneficial. Its administration renders expectoration much easier. The patients thus become more comfortable and, as the mucus and cough diminish, may even become symptom free unless there are marked secondary changes (emphysema and bronchiectasis) or a fresh episode is encountered. The beneficial results may last for several months or longer.

The dose is usually one or sometimes two injections per week, and may be continued in conjunction with other approved treatment until the cough, wheezes and sputum are reduced to a minimum. It cannot be emphasized too strongly that intramuscular ether in oil is an adjuvant and that it is not intended to replace other therapeutic agents.

Three cases of chronic bronchial asthma were so treated. Expectoration increased considerably and, after four or five injections, the symptoms were markedly improved. In these cases, the administration of ether in oil was continued weekly for about three months.

Status asthmaticus This disease presents a most distressing clinical picture. The patients are in a state of constantly acute asthma and do not respond appreciably to medication. They are referred to as adrenalin fast cases. In these cases intramuscular ether in oil appears to be an excellent adjuvant. In about two or three hours following its administration, beneficial results may be noted. The patients become quieter, expectorate more freely and profusely, and other palliative medications become more effective. The dose, one ampule, should be repeated every four to six hours as indicated by the response and progress of the patient.

Two patients with status asthmaticus were treated. One received nine intramuscular injections of ether in oil, the other eleven. Although both these patients had chronic asthma and had never been completely free of their symptoms, one has remained symptom free for more than four months, and the other for more than six months.

SUMMARY

Ether in oil intramuscularly as an adjuvant for the treatment of bronchial asthma is suggested.

It appears to act as an anticonvulsant and expectorant, thus beneficially influencing the asthmatic state.

The good results obtained may last from several hours to several weeks or months and justify further clinical studies.

CLINICAL NOTE

SUCCESSFUL POST-MORTEM
CESAREAN SECTION

REPORT OF A CASE

RICHARD J. MORAN, M.D.*

CAMBRIDGE, MASSACHUSETTS

BECAUSE of the relative rarity of cases of successful post-mortem cesarean section, in the medical literature,¹⁻³ it is thought worth while to report the following case:

CASE REPORT

H. M., a 24-year-old gravida III para I, entered the Cambridge City Hospital on January 19, 1941, with a chief complaint of cough and difficult respirations. Three days previously she had noted onset of cough, sore throat, generalized muscle aches and low-back pain, together with dyspnea. These symptoms all regressed except the cough and dyspnea, which had grown steadily worse. The cough was productive of thick yellow sputum. The patient had had no chill, chest pain or hemoptysis. She was seen by her family physician, who advised hospitalization.

The patient had had bronchial asthma for the preceding 8 years without treatment. She had one living child, 3 years of age. Her second pregnancy had resulted in a stillbirth. Her last menstrual period occurred about June 20, 1940, so that on entry she was slightly less than 7 months in gestation. The prenatal care had been adequate. She was first seen on October 30, 1940, with a blood pressure of 90/60; it was noted that she was nervous and apprehensive. On December 11 the blood pressure had risen to 136/70. She had gained 9 pounds, her weight at that time being 228 pounds. She was seen on January 8, 1941, and had no toxic signs or symptoms; the blood pressure was 152/76, and the body weight 232 pounds. She was not seen again until the day of admission.

Physical examination revealed a well-developed, obese white woman lying propped up in bed, wheezing and coughing. The temperature was 100.4°F., the pulse 134, and the respirations 36. Both lung fields were diffusely filled with fine moist expiratory rales. Occasional coarse inspiratory rales were heard over the bases posteriorly. Expiration was prolonged. The abdomen was obese, and there was a midline tumor mass extending two thirds of the way to the ensiform cartilage. The fetal heart was audible in the right paraumbilical region and was regular. The diagnoses at that time were seven-month pregnancy, bronchial asthma and grippe.

The patient was immediately given adrenalin, intravenous aminophyllin, calcium gluconate and 50 cc. of

*Formerly, intern, Cambridge City Hospital.

50 per cent glucose intravenously, but respiratory distress continued. She was put into an oxygen tent. A portable chest plate was taken, the report being: "Mottled areas of increased density scattered throughout both lung fields. The appearance is consistent with an extensive bilateral bronchopneumonia." Sputum typing and blood culture were immediately done, and both were reported positive for Type 3 pneumococcus. Type 3 rabbit serum was obtained from the Massachusetts Department of Public Health, and the patient was skin-tested. The reaction was markedly positive to a 1:1000 dilution, and an ophthalmic test was positive to a 1:100 dilution. Advice was sought from Dr. Maxwell Finland of the Pneumonia Service of the Boston City Hospital. He emphatically advised that serum should not be given, and it was therefore withheld. Sulfathiazole was given in full therapeutic dosage.

On the morning of the 4th hospital day the patient was seen by the Obstetrical Service. They advised discontinuing the pregnancy and treating the pneumonia, but added that in the event of death a post-mortem section should be considered. On the same day the patient rapidly became worse. The temperature rose to 105°F., and the pulse was over 160. The color remained good,—in the oxygen tent,—but the patient became comatose at about 11 p.m. Coarse moist rales were audible throughout both sides of the chest, and the fetal heart could not be heard in the presence of the loud gurgling respirations.

In spite of constant and energetic measures to restore the patient, she failed to rally, and preparations were hastily made for a post-mortem cesarean section. Terminally the respirations became short gasps with long intervals of apnea. The oxygen tent was kept going continuously, and the patient's color remained good. She was pronounced dead at 3:24 a.m., no fetal heart sounds having been heard for about 4½ hours. About 20 seconds later the abdomen was opened by a single midline incision, and the uterus sagged forward. The fundus was opened, and the baby was delivered manually. A small incision was inflicted on the baby's right cheek by accident when the uterus was opened. Alpha-lobeline was injected into the umbilical cord, which was apparently pulseless, and within a few seconds respirations were established. The infant, a female, was transferred to an incubator, and given oxygen as needed. Vitamin K was given and gavage feeding was begun within 24 hours. The early feeding consisted of water, glucose and whisky, later supplemented by breast milk.

At birth the infant weighed 3 pounds, 6 ounces. After an initial loss of 2 ounces in weight she made uneventful progress. She left the hospital after 7 weeks, weighing 6 pounds, and is at present in good health.

MEDICAL PROGRESS

THE SULFONAMIDES**

I. Their Mode of Action and Pharmacology

CHARLES A. JANEWAY, M.D.†

BOSTON

IT IS six years since Prontosil, synthesized by I. Mietzsch and Klarer¹ and proved to be effective against the hemolytic streptococcus in mice by Domagk,² first came to the attention of the English speaking medical world as a potent chemotherapeutic agent in man, with Colebrook and Kenny's³ report on its use in puerperal sepsis. There have been few more important medical discoveries, and it can be truthfully stated that the introduction of the sulfonamide drugs marked the beginning of a new era in medicine. Bacterial infections, most of which had been treated by purely symptomatic measures, suddenly became amenable to therapy, and the reduction in the mortality of such severe infections as hemolytic streptococcus meningitis, pneumococcal pneumonia and meningococcal meningitis has been little short of miraculous.

It is small wonder that there has been a flood of papers on the use of the sulfonamides or that those in practice have been somewhat confused by the rapidity with which the popularity of one new sulfonamide derivative after another has waxed and waned. The only justification for adding this report to the multitudes already written is that I have been struck by the need for a very concise and practical presentation of the present state of our knowledge of these drugs.† In this and the following article, an attempt will be made to summarize what has been learned in six years about their usefulness and limitations and to put this information in such a form that it will be helpful to those who are called on to use the sulfonamides in everyday practice. This type of presentation must necessarily be somewhat dogmatic. Since the sulfonamides play such an important role in both civilian and military medicine, the times will justify the repetition in condensed form of what

can be found in the writings of many workers in the field of chemotherapy.

MODE OF ACTION

The intelligent use of these drugs presupposes an understanding of their mode of action. *There is overwhelming evidence that they act on the organisms to delay or completely to inhibit their multiplication and do not increase the defensive powers of the host.*

Resistance to pyogenic infections depends on the speed and intensity of the inflammatory reaction, which localizes the infection nonspecifically, and on the presence of specific antibody, which makes possible the destruction of organisms by phagocytosis or lysis. There is no evidence that the sulfonamide drugs act through either of these mechanisms. Nonspecific inflammatory localization is promoted by the time honored measures of heat and rest, the former to increase circulation to the inflamed area, the latter to keep the drainage of lymph at a minimum and to allow minute thrombi to form about the focus in lymphatics and capillaries. Specific antibody may be administered when it is lacking, as in the serum treatment of pneumonia.

The virulence of pathogenic organisms, however, depends not only on their ability to secrete substances that inhibit inflammatory localization, such as streptococcal fibrinolysin, and their ability to escape destruction by the phagocytes in the early stages of infection, but also and above all on their ability to multiply in the tissues of the host. This property is fundamental to all pathogens, and the most invasive bacteria, such as those of anthrax and plague, are able to utilize the substances in the body fluids of the host so effectively that they multiply at an astonishing rate and overwhelm their victim. The sulfonamides attack this aspect of virulence. If a sufficient concentration of a sulfonamide drug is added to a tube of culture medium, the growth of susceptible organisms is inhibited. If sufficient concentration of a sulfonamide is present in the body fluids of the patient, these fluids become poor mediums for the growth of many species of micro-organisms, and thus infections with these organisms may be brought under control, by what amounts to a process of starvation of the

Reprints of articles in this series are not available for distribution but the articles will be published in book form. The current volume is *Medical Progress Annual Vol. III 1942* (Springfield Ill no. 3 Charles C. Thomas Company 1942 \$5.00).

*From the Medical Clinic, Peter Bent Brigham Hospital and the Department of Medicine and of Bacteriology and Immunology, Harvard Medical School.

**There is one excellent manual which every practicing physician would do well to own. *Guide to Therapy for Medical Officers*, War Department Technical Manual 8-210 obtainable from the United States Government Printing Office, Washington, D. C., for 25 cents. Section V (pages 110-135) covers sulfonamide chemotherapy briefly and accurately.

bacteria. However, the organisms are often only starved into submission, and their release from the inhibitory activity of the sulfonamide before the body's defenses have been able to localize them or destroy them, or before the bacteria have autolyzed, is followed by rapid multiplication and the return of signs of infection.

The most important observation on the mode of action of these drugs was the finding by a number of workers⁴⁻⁷ that there are substances capable of inhibiting the bacteriostatic action of the sulfonamides. The only inhibitor substances that have been identified chemically are para-aminobenzoic acid and its esters, among which is procaine. These substances have been found in killed and autolyzed bacteria,⁵⁻⁷ yeast,⁸ autolyzed liver, pus and other tissue-breakdown products.^{9,10} MacLeod's demonstration of the presence of sulfonamide inhibitor in pus and of its absence from serum explains the marked difference in therapeutic response between rapidly spreading infections such as pneumonia and localized purulent foci such as empyema.¹¹ It is a point of great theoretical interest that just as only the para-form of aminobenzene-sulfonamide is effective against bacteria, whereas the meta-isomers and ortho-isomers are relatively inert, so the para-form of aminobenzoic acid alone of its isomers possesses the ability to inhibit sulfonamide action.⁸

In vitro study of the effect of sulfonamides on bacterial growth has shown that the curves have the character depicted in Figure 1. At first, in the period A-B, growth takes place at the normal rate. This is known as the "lag" phase. At B some change occurs, and from B to C is the period of *bacteriostasis*. Under proper conditions the population may fall in the period C-D, and the bacteriostatic effect can be said to have been sufficient to become *bactericidal* (Curve 1). Under other conditions the events depicted by Curve 2 may occur, and there is a phase of "escape."

Two mechanisms may make this escape possible. Enough organisms may autolyze to liberate sufficient inhibitor substance into the medium to overcome the sulfonamide effect, or drug-resistant organisms may develop, capable of growing in the presence of the drug. Such drug-fast strains can be produced by passing organisms through mediums containing increasing concentrations of the drug.¹²⁻¹⁴ That drug-fastness depends on the ability to synthesize more para-aminobenzoic acid is suggested by the observation that drug resistance does not develop in the presence of small amounts of the acid^{13,15} and by the studies of Mirick,¹⁶ which showed that a drug-resistant pneumococcus synthesizes ten times as much para-aminobenzoic

acid as its parent strain. In actual clinical practice, the development of sulfonamide resistance has been

FIGURE 1. Schematic Representation of Normal Growth Curve of a Micro-Organism and Its Growth Curve in the Same Medium Containing an Effective Concentration of a Sulfonamide Drug.

observed only a few times,^{15, 17, 18} but the fact that it may develop is an argument for treating infections intensively at the beginning.

The lag phase corresponds to the clinical observation that there is a period of several hours after chemotherapy is begun before a therapeutic effect is noticeable. This suggests that some change must occur either in the bacteria or medium during this period. There is proof that this change involves the organisms and not the medium, and that it is readily reversible.^{19, 20} Recently Rose and Fox²¹ have suggested that it is due to the exhaustion of a substance present in the parent bacteria, which cannot be synthesized by the bacteria in the presence of sulfonamide. Their evidence for this is that, at the minimal effective sulfonamide concentration, the bacteria divide only a fixed number of times before inhibition of growth occurs, no matter what the size of the inoculum or the character of the medium, provided it does not contain para-aminobenzoic acid.

In 1940, Fildes²² propounded his theory that the sulfonamides and other antibacterial substances act by interfering with the metabolism of an essential metabolite ("an organic substance without which metabolism cannot proceed to the extent required by growth"). Since that time a series of papers from his laboratory have built up a convincing array of evidence for this hypothesis, and have placed the further development of sulfonamide therapy on a rational rather than an empirical basis.

Woods⁸ identified para-aminobenzoic acid as the specific inhibitor of the action of the known sul-

fonamides. From his work, he suggested that sulfanilamide, by virtue of its chemical similarity to para-aminobenzoic acid, replaces the latter as the substrate for an enzyme concerned with the further utilization of this essential metabolite. Whether or not bacteriostasis or growth occurred in such a system, depends on the relative proportion of the two competing substrates. If the proportion of para-aminobenzoic acid to sulfanilamide was more than 1:5000, growth occurred; if less, growth did not, regardless of the absolute concentrations of either substance. Such a theory of competitive inhibition still does not explain why the critical ratio of para-aminobenzoic acid to sulfanilamide is 1:5000 with a given strain of micro-organism whereas the ratio of para-aminobenzoic acid to sulfathiazole with the same strain is 1:3, but it explains all other known facts very well. A partial explanation, at least, for the differences in bacteriostatic efficiency of the various sulfonamide drugs has been offered by Fox and Rose.²³ They found that the critical ratio of para-aminobenzoic acid to sulfonamide was much more nearly the same for the different drugs if only the concentration of ionized sulfonamide was considered. Schmelkes and his co-workers²⁴ have come to the conclusion that the active sulfonamide exists as an anion, and recently Cowles²⁵ has reported evidence further strengthening the hypothesis that ionization plays a decisive role in sulfonamide action.

One necessary assumption is that para-aminobenzoic acid is an essential metabolite for bacteria. Evidence for this has been provided by Park and Wood,²⁶ who showed that, in the presence of biotin, extremely minute amounts of para-aminobenzoic acid produced a marked stimulation of growth of *Clostridium acetobutyricum*. A practical application of the identification of para-aminobenzoic acid as a specific inhibitor of the bacteriostatic action of the sulfonamides is its inclusion in culture mediums so that organisms present in the blood and other body fluids of patients under sulfonamide therapy will grow at a normal rate.²⁷

On the basis of Fildes's general theory and Woods's elaboration of it for the sulfonamides, it should be possible, from a knowledge of bacterial metabolism, to prepare chemotherapeutic agents which will inhibit the utilization of other essential metabolites. The validity of the hypothesis has been tested and supported in experiments conducted by Fildes's associates. By replacing a carboxyl group on an essential metabolite with a sulfonic group, the utilization of the metabolite may be competitively blocked by a sufficient concentration of the new and unnatural, but chem-

ically similar compound. A list of those compounds already tried follows:

AUTHOR	ESSENTIAL METABOLITE	GROWTH-INHIBITOR
Woods ⁸	Para-aminobenzoic acid	Sulfonamides
McIlwain ²⁸	Nicotinic acid	Pyridine-3-sulfonic acid
McIlwain ²⁸	Nicotinamide	Pyridine-3-sulfonamide
McIlwain ²⁹	Alpha-amino-RCOOH	Alpha-amino-RSO ₃ H
McIlwain ³⁰	Pantothenic acid	Pantoyl taurine
Fildes ³¹	Indole; tryptophan	Indolacrylic acid

McIlwain³⁰ has proposed what he has called the antibacterial index for characterizing such systems. This is the ratio of the minimal effective concentration of the bacteriostatic agent to the concentration of the corresponding metabolite. Such a ratio is constant for any particular organism, although the absolute amounts of the two substances may vary over a wide range. The determination of such ratios, of course, involves the use of synthetic culture mediums of known composition, so that the concentrations of the substances being tested can be accurately measured. From a knowledge of such a ratio, of the concentration of the essential metabolite in tissue fluids and of the toxicity and absorption of the bacteriostatic substance, it should be possible to determine whether or not a new chemotherapeutic agent of this type can be expected to work in vivo against a particular organism.

Thus, in seven years, chemotherapy has progressed from the more or less empirical discovery of an azo-dye, Prontosil, to the synthesis of new chemotherapeutic agents which can be designed to attack the most vulnerable facet of an organism's metabolism. It should not be forgotten that none of this progress would have been possible had not the laborious work of elaborating the growth requirements of bacteria been going on for many years. It is largely due to the work of men like Fildes in England and Mueller in this country that the science of bacteriology has been carried forward to the point where it can provide the tools for the further development not only of the field of chemotherapy, but of human nutrition as well.

PHARMACOLOGY OF SULFONAMIDE DRUGS

Besides an understanding of the way in which the sulfonamides act on bacterial infections, it is essential for a physician who uses these drugs to have accurate knowledge of their pharmacology. When drugs such as aspirin are used for the relief of symptoms, little more knowledge than the average layman possesses is necessary, but when poten-

tially dangerous remedies are used in large doses for the treatment of serious diseases, detailed pharmacologic knowledge is as vital to the physician as are a knowledge of anatomy and a skilled technic to the surgeon performing a difficult operation.

The pharmacology of these drugs can best be presented in tabular form after a few general remarks. All the sulfonamides in common use are derivatives of sulfanilamide, which has this formula:

The numbers after the hydrogen atoms are to identify them for convenience in the text.

Two types of sulfanilamide derivative have come into clinical use. The first type involves a replacement of hydrogen atom (4) by some nucleus, from which the compound derives its name. Thus, sulfapyridine consists of sulfanilamide with hydrogen (4) replaced by the pyridine ring. These com-

side of the vein. However, at 0.5 per cent strength they may be used subcutaneously in infusions.* *They must never be used intrathecally, as their alkalinity will produce irreparable damage to the nervous tissue.*

A second type of sulfanilamide derivative has been introduced by Marshall and his associates³² as a result of their studies of sulfaguanidine, which was synthesized by Roblin and his co-workers. Sulfaguanidine is water-soluble to a considerable degree, but is absorbed very poorly from the bowel, so that high concentrations of the drug in the intestinal tract may be achieved while the blood level remains low. While sulfaguanidine involves a substitution of a guanidine radical for hydrogen atom (4), succinyl sulfathiazole, which is now being tested for its effect in the bowel, has a succinic acid chain coupled to the para-amino group replacing hydrogen (2). In the bowel the succinic acid is split off, liberating sulfathiazole, which is more potent than sulfaguanidine and is comparatively little absorbed in the large intestine.³³

The present knowledge of the distribution of these drugs is the result of the development of ac-

TABLE 1. Characteristics of the Sulfonamide Drugs.*

DRUG	RATE OF ABSORPTION	DEGREE OF CONJUGATION	RATE OF EXCRETION		DESIRED BLOOD LEVEL	SURJECTIVE DISCOMFORT	INCIDENCE OF COMMON TOXIC SYMPTOMS			
			FREE	CONJUGATED			NAUSEA AND VOMITING	ACUTE HEMOLYTIC ANEMIA	MILD ANEMIA	GRANULOCYTOPENIA
					mg./100 cc.					%
Sulfanilamide	Rapid	Usually about one third	Rapid	Fairly rapid (soluble)	8-15	Very frequent	Frequent	Fairly frequent (2-3%)	Almost constant	<1
Sulfapyridine	Irregular	Usually high	Moderately rapid	Slow (moderately insoluble)	5-10	Frequent	Very frequent	Rare	Frequent	<1
Sulfathiazole	Rapid	Usually less than one third	Very rapid	Rapid (very insoluble)	3-7	Rare	Frequent	Very rare	Rare	<2
Sulfadiazine	Fairly slow	Usually less than one third	Slow	Moderately slow (soluble)	8-15	Very rare	Rare	Rare	Moderately rare	<1

*Percentages where used are from Long's³² published statistics.

pounds are all more potent than sulfanilamide. However, they are much less soluble, and for that reason they are unsuited for parenteral use. The substitution of a sodium atom for hydrogen atom (3) renders them soluble in high concentrations and they may be injected intravenously as 5 per cent solutions in distilled water or saline solution. Thus the formula for sodium sulfadiazine is:

These sodium salts are quite alkaline and are extremely irritating if injected into the tissues out-

curate methods for their estimation by Fuller³⁴ in England and by Marshall and his co-workers³⁵ in this country. The method depends on the fact that sulfanilamide or its derivatives when coupled to N-(1-naphthyl)-diethyleneamine develops a purple-red color. This reaction is specific for the para-amino group and is accurate except in the presence of procaine, which is an ester of para-aminobenzoic acid. If, for example, novocain is allowed to enter the pleural cavity in preparation for thoracentesis, the fluid removed may appear to contain much larger amounts of sulfonamide than it actually does.

The important facts that should be known about each sulfonamide are its rate of absorption

*There is recent evidence that concentrations as high as 2 per cent are tolerated on subcutaneous injection

and rate of elimination, since on the balance between these depends the level achieved. Absorption of the substituted sulfonamide takes place mainly in the stomach. It is modified by food, and is most rapid before meals but most complete after meals.³⁶ Alkali may play a role in increasing the amount absorbed. Elimination may occur in two ways, either by excretion of the unchanged or free drug in the urine or by conjugation of the free drug to a combined form, probably in the liver. The conjugated form, which has little therapeutic activity, is excreted in the urine also.

The determination of the amount of conjugated sulfonamide present is made by determining the free drug in the usual manner, then hydrolyzing the sample with heat and acid for one hour, which

Toxic effects follow a general pattern for the whole group, with some differences between individual drugs.

Nervous symptoms are always present to greater or less degree, and usually appear soon after therapy is begun. These vary from mild lassitude or anorexia through nausea and vomiting to frank psychosis. Nausea and vomiting are listed as nervous, since they are clearly central in origin. The mechanism of these symptoms is not yet clearly understood, although it has been suggested that they represent subjective reflections of disturbances in metabolism of nervous tissue produced by the drug. In any case, acute poisoning of animals with large doses of the sulfonamides results in convulsions and spasticity, evidences that the central nervous system has suffered most severely. Various vitamin preparations, particularly nicotinic acid, and oxygen have been recommended for their control, with different results in the hands of different investigators. The advent of sulfadiazine, which produces very little subjective disturbance, has made such accessory therapy unnecessary. An important practical point is that an ambulatory patient taking sulfonamides should be warned that his reaction time may be slowed. Special care should be observed in driving a car, crossing streets and performing manual work.

*Acidosis** occurs only when sulfanilamide is used, since it is associated with inactivation of the enzyme, car-

TABLE 1 (continued).

INCIDENCE OF HYPERSENSITIVITY		TENDENCY TO SENSITIZE	INCIDENCE OF RENAL COMPLICATIONS	COMMENT
RASH	FEVER			
%				
2	Frequent (10%)	Moderate	Very rare	Se'dom used because of subjective discomfort, low potency and anemia
2	Fairly frequent (4%)	Slight	Hematuria, fre- quent, oliguria, occasional	Potent, but se'dom used because of vomiting and irregular absorption
5	Very frequent (10% or more)	Marked	Hematuria occa- sional oliguria, frequent	Very potent and well tolerated but most apt to cause renal complications and to sensitize, causing rash and fever on subsequent administration. Difficult to maintain desired blood level because of rapid excretion.
2	Moderately rare (2%)	Slight	Hematuria, occa- sional, oliguria, rare.	Not quite so potent, but best tolerated and high blood levels easily achieved because of slow excretion. Treacherous since serious toxic reactions may occur after cessation of therapy, also owing to slow excretion.

converts the conjugated to the free form, and re-determining the amount of drug.

The distribution of these drugs within the body varies considerably. This may depend in part on differences in ionization already mentioned, but even more on the binding of the different drugs by the proteins of the plasma, as demonstrated by Davis.³⁷ At one extreme, sulfanilamide appears to traverse membranes with little difficulty and is found in the red cells and in the spinal fluid in concentrations similar to those in plasma, whereas at the other extreme, sulfathiazole remains chiefly in the plasma, appearing in both red cells and spinal fluid in considerably lower concentrations. In most inflammatory exudates, these drugs are found in concentrations closely approximating those of the blood.

Lonic anhydrase. This inactivation has been shown to be due to the sulfonamide group and not to the para amino group on which antibacterial activity depends.^{39, 40} In the substituted sulfonamides the sulfonamide group is covered by the substituent nucleus, and thus cannot react with the enzyme. Bicarbonate of soda diminishes acidosis with sulfanilamide, but is not necessary with the other drugs.

Cyanosis, so prominent and unsightly a manifestation of sulfanilamide therapy, is slight with the other drugs. It has been proved to be due to a combination of methemoglobin⁴¹ and the colored oxidation products of sulfanilamide, some of which are responsible for the oxidation of hemoglobin methemoglobin.⁴² It can be reversed by the reducing action of methylene blue,⁴³ but usually does no harm. However, the production of methemoglobin by

*This acidosis is characterized by a loss of sodium ions in the urine and a reduction of the bicarbonate and sodium ions and an increase of the chloride ions in the plasma. With this clinical picture, hyperventilation develops. These changes are reversed when the drug is stopped. Bicarbonate of soda acts only as a symptomatic remedy that relieves the hyper-ventilation to some extent.

sulfonamide therapy is of possible importance in aviation medicine. Methemoglobin will not carry oxygen, and aviators undergoing chemotherapy should suffer from anoxia at lower altitudes than normal men. Since anoxia is one of the chief limiting factors in aerial combat, these men should be grounded until they are well.

Blood disturbances are all too common and may assume almost any form. Acute hemolytic anemia, which may be severe enough to cause hemoglobinuria, is rare except with sulfanilamide. It generally comes on in the first few days of therapy. This type of anemia can be produced by many chemically related substances, notably para-aminophenol,⁴⁴ which may possibly be produced in vivo from sulfanilamide. Low-grade anemia, which may be remedied by transfusion, is a common accompaniment of prolonged sulfonamide therapy. The granulocytes are particularly sensitive to many compounds derived from benzene, and therefore agranulocytosis and granulocytopenia may occur with all these drugs. Thrombocytopenia, with purpura, likewise has been described with all the drugs in common use, although it is extremely rare.

Skin manifestations are manifold. Various types of erythematous eruptions—particularly morbilliform or nodose—have been observed. A few cases of exfoliative dermatitis have followed sulfonamide therapy. These rashes frequently accompany fever, lymphadenopathy, splenomegaly and arthralgia, to form a picture quite comparable to serum sickness. Furthermore, these toxic reactions occur most frequently from the fifth to the fifteenth day after the beginning of therapy, and if a patient once has such a reaction, the readministration of a small dose of the drug will suffice to precipitate the reaction in the space of a few hours. This phenomenon is analogous to that of accelerated serum sickness.

Fever is one of the commonest and most confusing toxic reactions, especially when it occurs without rash, arthralgia or lymphadenopathy. Its mechanism is not understood any better than that of other drug sensitivities, such as the ninth-day erythema of arsphenamine treatment, to which it is entirely comparable. As yet nobody has been able to demonstrate the presence of specific antibodies in patients who develop this form of hypersensitivity. An attempt to transfer hypersensitivity passively to normal people with the serum of the most sensitive patient observed was entirely unsuccessful.⁴⁵

Visceral damage may occur in sulfonamide therapy. Hepatitis with jaundice has been reported, but it is very rare. Renal damage simulating the nephrosis of bichloride poisoning may occur with rather small doses of sulfathiazole and probably represents a true toxic nephritis.⁴⁶ Myocardial lesions occur pathologically in patients receiving sulfathiazole, and intraventricular block has been observed in a patient with severe intoxication.^{45, 47} One or two cases of encephalopathy from sulfathiazole have been reported, and are possibly analogous to the hemorrhagic type of encephalitis, which is a rare but very severe form of intoxication with the organic arsenicals.

Oliguria due to precipitation of the drug has been observed only with the relatively insoluble substituted sulfonamides and not with sulfanilamide, which has a relatively high degree of solubility. As the glomerular fil-

trate passes down the renal tubules, it is concentrated by the resorption of water. This may result in a concentration of the urine to a point where the solubility of the sulfonamide or its acetylated form is exceeded and precipitation occurs.* Hematuria, calculus formation or tubular obstruction may result, with consequent oliguria and eventual renal shutdown unless something is done quickly to prevent it.

That sulfonamide therapy produces not only functional and chemical disturbances in the patient, but morphological changes as well, has recently been conclusively proved. A number of authors⁴⁶⁻⁴⁸ have described multiple small nodules of miliary necrosis in the tissues of patients receiving sulfathiazole. Rich,⁴⁹ in an investigation of the pathology of serum sickness, has described lesions indistinguishable from those of periarteritis nodosa. It is significant that most of his patients had received sulfonamides as well as serum and that he found similar lesions not only in a case of serum sickness before the days of chemotherapy, but also in a patient who had received nothing but sulfathiazole. If this finding can be substantiated, it will provide pathological evidence for the essential similarity between the hypersensitivity developing as a result of sulfonamide administration and that following foreign serum.

The pharmacologic properties of the individual sulfonamide drugs are assembled in Table 1 in such a way that they are readily available for the physician who must choose which drug he will use. When the individual drugs are compared, certain differences between them do stand out clearly. Sulfanilamide is conspicuous for the frequency of cyanosis, acidosis and acute hemolytic anemia. Sulfapyridine is characterized by two outstanding properties—its tendency to produce nausea and vomiting and its antipyretic action.^{50, 51} Of all the drugs in this group it is the only one which is antipyretic, and thus temperature is not a reliable criterion for control of infection with sulfapyridine. Sulfathiazole and sulfadiazine are both remarkably well tolerated by most patients. However, there is increasing evidence that sulfathiazole is a fairly toxic drug, and unfortunately, sulfadiazine, although it produces severe reactions less frequently, is treacherous because of its slow excretion.

*Bicarbonate of soda has been recommended to make the urine more alkaline and thus prevent crystal deposition. It is doubtful whether the urine can be rendered sufficiently alkaline to alter markedly the solubility of these compounds. Soda may be given when hematuria or oliguria occurs, but its routine administration is not justified, because these patients already have to take so many pills.

CASE 28521

PRESENTATION OF CASE

First admission. A twenty-three-year-old single English typist was admitted because of chronic productive cough of thirteen years' duration.

Nineteen years prior to admission the patient suffered with a severe attack of whooping cough. The cough persisted for a year and finally cleared up spontaneously at a seashore resort. During the succeeding seven years she had recurrent colds, sore throats and several episodes of "draining ears." Her "tonsils and adenoids were snipped" several times, and following the last tonsillectomy twelve years ago, she developed a chronic cough. During the next ten years the cough gradually became severer and more productive so that at the time of admission she raised half to three quarters of a glassful of foul-smelling greenish sputum each day. The greatest amount was raised in the morning and in the evening on return from work. The patient had recently noticed blood streaking of the sputum, and at times she expectorated large tenacious plugs. She attempted postural drainage, but this proved too strenuous for her.

Four years before entry many nasal polyps were removed. Two years previously a radical antrum drainage was established without improvement. At that time, she suddenly developed severe sharp pain in the left chest. Her physician believed that she had pleurisy and accordingly immobilized the chest with adhesive strapping, but this provided little relief. Two weeks later, x-ray examination apparently demonstrated a collapsed left lower lobe. A lipiodol study revealed bronchiectasis of the left lower lobe. Three weeks before entry, following an episode of coughing, she raised a quart of blood, but there had been no recurrence of the massive hemoptysis.

The family and past histories were noncontributory.

Physical examination disclosed a poorly nourished, asthenic girl in no acute distress. Examination of the heart was negative. A few coarse rales were audible over the entire left lung posteriorly.

The blood pressure was 130 systolic, 90 diastolic. The temperature was 98, the pulse 90, and the respirations 20.

Examination of the urine revealed a +++ test for albumin. A review of the chest x-ray films after lipiodol instillation, taken at another hospital, showed left-lower-lobe bronchiectasis. No disease was seen in the left upper lobe and right lung.

The patient was discharged unimproved on the third day after admission.

Second admission (four months later). A left lower lobectomy was performed. The patient had a stormy postoperative course. She developed atelectasis of the left upper lobe and encapsulated empyema at the apex. Bronchoscopy revealed a great amount of mucus in the left bronchus, but no mucous plug was seen obstructing the bronchus to the upper lobe. The empyema was tapped, and very small amounts of thick material were recovered. This fluid was negative on culture.

Eight weeks after lobectomy, the left third rib was resected, and open drainage established. Multiple pockets containing air and a thin clear fluid were found over the anterior and superior surfaces of the upper lobe. After this, the temperature and pulse, which had been elevated slightly each day, gradually returned to normal. The patient was discharged four months after admission.

Third admission (one month later). One week after discharge the lobectomy incision opened at the lower end and discharged a mucoïd material. The patient had a slight fever, and her physician inserted a tube in the wound for drainage. The upper empyema-drainage tube discharged a moderate amount of pus. The patient was emaciated and appeared to be chronically ill. There were three tubes in the left chest wall, two in the third intercostal space and another in the sixth intercostal space. An x-ray film of the chest revealed the tip of the upper drainage tube lying anteriorly and the lower tube posteriorly in the chest. There was still density throughout the entire left lung field except for a small collection of air at the extreme apex. The heart shadow was still markedly displaced. The patient gradually improved on open chest irrigation and left the hospital a month later.

Fourth admission (two years later). Following discharge the patient soon developed empyema on the right side, which was drained by tube at home. She spent the greater part of the next three months in an oxygen tent at home. A slow recovery was made and she was not out of bed to any extent till the following summer — about a year later. The patient then moved to a farm, where improvement was marked. Her weight rose from 65 to

98 pounds, her appetite increased, she felt stronger, and her cough lessened. She continued, however, to produce about 100 cc of foul sputum daily. She had had slight hemoptysis on only three occasions in the previous few months. Occasionally

communicating with a dilated left main bronchus. The left lower main bronchus ended abruptly, apparently at the site of the lobectomy. The mediastinum was displaced to the left but showed no respiratory shift. The right lower lung field showed

FIGURE 1 Roentgenogram Taken at the Fourth Admission Showing the Apparent Pneumothorax in the Apical Portion of the Left Pleural Cavity

she had pains in her left upper chest, accompanied by a "congested feeling," anorexia and a "dragged out sensation." Her symptoms were progressive to the time of admission.

Physical examination showed dullness, increased tactile fremitus and decreased breath sounds over the left upper lobe. Over the left lower lobe there were dullness, flatness and absent breath sounds and tactile fremitus. There were a few rales at the right base. The fingers were clubbed.

X-ray films showed that the lower half of the left lung field was completely opaque and that there apparently was a pneumothorax occupying the apical portion of the left pleural cavity (Fig 1). In the left midchest were several rounded areas of diminished density, without fluid levels, commu-

nicating with some apparent honeycombing, which had the appearance of bronchiectasis. In the lateral view this was seen to occupy the region of the middle lobe.

An operation was performed on the seventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR JOHN W. STRIEDER * This is a long case and demonstrates many of the vicissitudes through which a patient who has had some of the complications of major thoracic surgery goes. It is probably better to take it up in sections and to comment as we go along.

* Visiting surgeon for thoracic surgery, Boston City Hospital and Massachusetts Memorial Hospital.

What is the significance of the attack of whooping cough? I think that is difficult to say without entering into a long discussion of the etiology of what may be the final diagnosis. The cough persisting for a year and then clearing up suggests that the patient had pulmonary disease that antedated the attack of whooping cough.

The tonsillectomy, twelve years previously, brings up the question of its relation to the subsequent course. She had no acute episode following tonsillectomy as she would have had had she developed putrid or nonputrid lung abscess as a result of the aspiration of infected secretions. The fact that the cough gradually became more severe "during the next ten years," in other words that she survived that ten years of cough, seems to me to be against acute lung abscess as a complication at that time. She raised more sputum in the morning and evening, which is usual because patients with chronic pulmonary suppuration have an opportunity during those twelve-hour intervals of puddling secretions and subsequently raising large amounts. She coughed up tenacious plugs, which may well have been fibrinous casts. It is interesting that, in patients with bronchiectasis, chronic sinusitis is a common complication that goes hand in hand with it. As Dr. Churchill has suggested, bronchiectasis is simply another infected sinus.

The question whether the atelectasis arose as a complication of the antral operation comes up. I should like to know what the anesthesia was. However, we all realize that atelectasis can be a complication of any surgical procedure under any anesthesia, whether local or general.

Hemoptysis of a quart of blood, of course, is not unusual in various types of chronic pulmonary disease, particularly bronchiectasis. Hemoptysis as a complication of bronchiectasis is commoner than hemoptysis as a complication of pulmonary tuberculosis. Since I have never seen a fatal hemoptysis in a patient who has bled as a complication of bronchiectasis, it must be very rare. It usually suffices to stimulate the patient to seek treatment, however, and in that connection it often serves a purpose.

The +++ test for albumin with the chronic pulmonary situation suggests chronic amyloidosis.

May we see the bronchograms? I do not know what Dr. Robbins will think of them, but to me, with the exception of the lateral view made earlier at another hospital, they contribute very little.

DR. LAURENCE L. ROBBINS: I think there is definite evidence of bronchiectasis in the left lower lobe.

DR. STRIEDER: These oblique views do not show it. Do you think that is something down there, below the shadow of the diaphragm on the left?

DR. ROBBINS: No; that is possibly an artefact. If it is anything of significance it is very poor filling.

DR. STRIEDER: The anteroposterior view, without lipiodol, shows atelectasis and that is all.

DR. ROBBINS: Yes. In addition to a very slight shift of the mediastinum to the left there is a dense line of increased density, which is consistent with a collapsed lower lobe.

DR. WILLIAM B. BREED: Do you mean to say that that dense line is the left lower lobe in its entirety?

DR. ROBBINS: No; but it is the sign that shows the edge of the collapsed lobe. Here is the triangular area of density that extends to the hilus, and this line is the edge of the lobe.

DR. STRIEDER: Up to this point the story is that of bronchiectasis. One thing not mentioned is bronchoscopy. To rule out the possibility of underlying foreign body, of bronchial adenoma or of other tumor, even in so young a patient, I make it a routine, in my clinic, to perform bronchoscopy on all patients with bronchiectasis. After lobectomy was done, bronchoscopy was performed, but there is no mention made of any lesion except for abundant secretions in the left main-stem bronchus. Conceivably other lesions could be overlooked because we assume the bronchoscopy was done for aspiration, and under the circumstances it is understandable that a pre-existing lesion could possibly be missed. I think it is not necessary to have a so-called "mucous plug" in the bronchus to the left upper lobe to have atelectasis of that lobe. At that time the patient had had the left lower lobe removed, and secretions in the left main bronchus would occlude the left upper bronchus so that atelectasis could occur.

We must assume that the cultures of the so-called "empyema" persisted negative over the eight-week period during which she was observed, and that drainage was undertaken perhaps with reluctance. The operative findings were also unusual for empyema, that is, if it was empyema due to pyogenic or anaerobic organisms, which might well be a complication of lobectomy. It leads one to suspect that perhaps the pathologic process was intrapulmonary rather than intrapleural and that the drainage established was actually in the lobe.

The discharge of mucoid material suggests two things: first, that the patient had opened a bronchopleural fistula and that mucoid secretions were coming from the open bronchus and, second, that she had pulmonary cyst of some sort with a communication with the pleural cavity and in turn with the incision. The mucoid drainage then became purulent, which it might well do as the result

of drainage of some weeks' standing, but there is no mention that the pus was mucopurulent in character.

Probably there was no bronchopleural fistula. This patient could tolerate open drainage with irrigation, and it seems likely that she would have had severe cough and other unpleasant symptoms if there was an open bronchus communicating with the cavity. So we are reduced to saying that either she had empyema without bronchopleural fistula, or that she had an intrapulmonary cyst without patent bronchial communications. While this preoperative film is up, I should like to ask Dr. Robbins if he attributes any significance to the suggestive annular shadow in the left apex.

DR. ROBBINS: It could be a bleb, but I cannot be positive on this film alone. I do not think it is a cavity.

DR. STRIEDER: It certainly suggests cyst, and I believe there is a pathologic process in the apex.

DR. ROBBINS: In fact there could be several small blebs in a group.

DR. STRIEDER: This was the first-admission film, and I point out the suggestion of an annular shadow in view of what is to follow.

DR. ROBBINS: For comparison this is a film taken on the last admission (Fig. 1) and shows what appear to be cavities in which there is fluid, as well as this larger one, which may be a loculated air cavity within the pleural cavity. Drainage tubes enter the chest. This is the area of resection for the lobectomy.

DR. STRIEDER: The fact that there was a large area of decreased density in the apex, anteroposteriorly, in a patient with atelectasis of the left upper lobe following left-lower lobectomy is not significant other than that this configuration is apt to denote pleural space in x-ray films. Under these circumstances I think we are justified in saying no more than that this was an intrapleural lesion.

We are therefore again thrown back on two possibilities: a residual intrapulmonary lesion, in view of the foregoing films, and an empyema without bronchopleural fistula. Despite the fact that the patient did not cough on irrigation, which is consistent with the latter, it seems to me unlikely that that was the situation.

I think we have to say there is a possibility of pulmonary cyst in the left upper lobe.

DR. ROBBINS: In this film, there is an air-filled space in the apex and there are several areas of rarefaction in the area of density in the left mid-lung field. These represent air-filled cavities. This could be air in the pleural cavity, but I think we have seen at least one case in which there was a

huge cavity in the apex that contained air, and one cannot very well tell the difference between them.

DR. STRIEDER: Can you offer any comment about this drainage tube entering into the intrapulmonary lesion?

DR. ROBBINS: Not from this film.

DR. STRIEDER: The anteroposterior view suggests to me that the lung is above the point of entrance of the drainage tube, and I think we have to take that into consideration, even though a lateral film is not available.

The problem resolves itself into a discussion of why, after left lower lobectomy for bronchiectasis, this patient continued to have symptoms of pulmonary suppuration and, as a corollary, what was the nature of these complications because of which she failed to improve. In such a complex situation the key to the solution, I think, lies largely in the x-ray films plus such other diagnostic procedures as we are able to apply, such as bronchoscopy. In this particular case, the result of bronchoscopy is not reported, but I think we can go along on supposition. If we can accept the report of the X-ray Department, based on films that are not here at the moment, there was bronchiectasis of the right middle lobe, which would account for the cough, and also intensive disease on the left side, and I think we are justified in assuming that the disability was due to the residuals in the remaining left upper lobe. The x-ray findings, the negative cultures of the material obtained on thoracentesis and the mucoid secretions strongly suggest cystic disease. Persistent atelectasis of the left upper lobe in a patient who has had left-lower-lobe lobectomy usually means obstruction of the bronchus by mucoid secretions or persistent underlying disease in the remaining lobe. That is, a patient whose remaining upper lobe stays collapsed after lower lobectomy, despite all measures to inflate it, usually has bronchiectasis or another related lesion in this lobe. On the information at hand I am unable definitely to rule out bronchial adenoma as a cause of the obstruction of the upper lobe, but I shall say that this patient probably had congenital cystic disease of the left upper lobe.

DR. TRACY B. MALLORY: Are there any questions or comments?

DR. BENJAMIN CASTLEMAN: Do you not think that, if she had congenital cystic disease of the upper lobe, the condition would have been at the first operation?

DR. STRIEDER: Not necessarily, for a variety of reasons. The upper lobe may have been completely held out by adhesions and the operator may not have thought it wise to explore farther,

knowing that the patient had disease in the left lower. Small cysts may not be palpable through surrounding normal lung tissue.

CLINICAL DIAGNOSIS

Bronchiectasis of left upper lobe.

DR. STRIEDER'S DIAGNOSIS

Congenital cystic disease, left upper lobe.

ANATOMICAL DIAGNOSIS

Cystic bronchiectasis of left upper lobe.

PATHOLOGICAL DISCUSSION

DR. MALLORY: I am sorry Dr. Churchill is not here to discuss this case since he could give us much additional information. He was able to mobilize the upper lobe readily and inspect it freely at the time he removed the lower lobe. He did not see any evidence of cystic disease and felt quite satisfied with the examination.

The major interest in this case is the anatomic finding in the upper lobe, after resection. The apex of the lung was occupied by an enormous cystic cavity. Across it ran a threadlike bridge, probably a persistent artery. In the lower part of the lung there were numerous ordinary bronchiectatic cavities, and between these cavities there was a great deal of fibrous pneumonitis and virtually no aerated pulmonary parenchyma. On the basis of the facts that at the time of the first operation it was possible to visualize the upper lobe quite well and that no suggestion of cystic disease was seen, Dr. Churchill and I believe that this must have been an acquired cyst or bronchiectatic cavity, not a congenital one, and that the period of this patient's history between the first and fourth admissions represents the time required for the development of an extreme grade of bronchiectasis. One could, of course, argue that some bronchiectasis was present at the time of the first operation, but I think it is safe to say that no massive cyst of this character could have been present. The specimen as it now appears is one that I think all pathologists who believe in congenital cystic disease would accept as such, and yet our own interpretation is the opposite. We think this was acquired bronchiectasis rather than cystic disease.

DR. STRIEDER: Would you be influenced by the fact that she did have persistent atelectasis, suggesting that she might have had previous bronchiectasis?

DR. MALLORY: It may be that the persistent atelectasis represents the cause of bronchiectasis. There is a great deal of debate on that point. I have always personally believed that persistent atelectasis is an important cause of bronchiectasis.

CASE 28522

PRESENTATION OF CASE

A sixty-two-year-old white male bundle clerk entered the hospital with the complaints of swelling of the legs and abdomen, dyspnea and frequent vomiting of three weeks' duration.

The patient dated the onset of his present illness from an accident nine months before when he slipped on a sidewalk curbing and sprained his right knee and ankle, which laid him up for five weeks. Following this period he was able to resume work and was comfortable in the daytime but was awakened several times every night by cramps in his calf. Six months previously he had developed a "dry eczema" on the dorsum of the left foot over the second and third toes. He described the lesion as a red spot the size of a five-cent piece containing many still redder spots within it. It did not hurt or itch. A change of shoes, suggested by a chiropodist, did not help, and the "eczema" slowly spread in the course of six weeks over the entire malleolus and up the internal aspect of the left calf. At that time a similar rash appeared on the dorsum of the right foot; then it in turn spread up the right leg at a rapid rate. Spots soon appeared above both knees, then on the outer aspects of both thighs, and the individual lesions began to coalesce. The lesions itched considerably but were not painful. Whitewash relieved the itching but not the spread of the lesions. During the following two months, lesions appeared in a spotty distribution over the abdomen, chest, shoulders and the flexor surfaces of the elbows and wrists. The patient observed that although these lesions in the upper part of his body were "rash-like" the ones below the knees became fiery red and blood seemed to collect beneath the skin. Vitamin B complex and haliver oil were given without improvement.

He then consulted another physician, who reported that his entire trunk and extremities were covered with a blotching erythema and an underlying fine purpura. The lower legs were studded with large perifollicular purpuric spots. There was also slight edema of the shins, and the right lower leg was distinctly swollen. A diagnosis of toxic erythema with purpura was made, and vitamin K was prescribed. The patient took 160 tablets over a period of forty days with apparent improvement; the rash disappeared from the trunk, arms and upper legs but persisted in purpuric form below both knees.

One month before entry, although the skin lesions had not changed in extent or character, the patient returned to his physician's office complaining of lower abdominal discomfort, nausea

and occasional vomiting of seven days' duration and abdominal distention of four days' duration. For seven days his legs had been swollen. His bowels had moved daily with the aid of his habitual "three quarters of an ounce" of milk of magnesia.

Physical examination at that time showed probable ascites and an icteric tint to the scleras. The hemoglobin was 14.6 gm., the red-cell count 5,000,000, and the white-cell count 6500 to 8600, with 74 per cent polymorphonuclears, 21 per cent lymphocytes, 4 per cent monocytes and 1 per cent eosinophils. The blood smear was not remarkable; the platelets were slightly decreased. The icteric index was 25, and the nonprotein nitrogen 30 mg. per 100 cc. The total protein was 6.15 gm., the albumin 3.58 gm. and the globulin 2.57 gm. per 100 cc. The bleeding time was 2½ minutes, and the clotting time 7 minutes, with normal clot retraction. The prothrombin time was normal. The corrected sedimentation rate was 8 mm. per hour. The blood Hinton reaction was negative. The urine showed a specific gravity of 1.020, with a slight trace of albumin and a slightest possible trace of bile by the foam and iodine tests. The sediment showed rare white and red cells and unnumerable hyaline and granular casts. A gastrointestinal series showed a normal stomach and duodenum; no esophageal varices were seen.

One week prior to entry it was found that the edema of his legs had progressed upward to the thighs. He complained of much unlocalized pain in both legs, especially on the left. An abdominal paracentesis was done, but the amount of fluid withdrawn and its character were not recorded. Digitalis and Salyrgan were prescribed.

The past history included severe poliomyelitis at the age of two and a half, with temporary paralysis of the entire right side of the body, followed by gradual return of motor function. The right extremities remained slightly weak, however, and scoliosis developed. The patient had an attack of jaundice at the age of twenty. The family history was noncontributory. He denied venereal disease and the use of alcohol. He had gained 13 pounds during the preceding year.

Physical examination showed an obviously ill and uncomfortable man with jaundice of the skin and scleras. Both lower legs were covered with purpuric spots, some of which appeared to be fresh; others were fading. There was pitting edema of both legs up to the knees, but the patient stated that this had decreased considerably during the previous week, during which he had received digitalis and Salyrgan. The spine showed marked scoliosis in the upper thoracic and lower cervical regions, and the chest considerable con-

sequent deformity. The size of the heart could not be determined by percussion, and the apex impulse was neither seen nor felt. The examiner's impression, however, was that it was not enlarged. The sounds were of fair quality, and the aortic second sound was recorded as equal to the pulmonary. There were no murmurs. The rhythm was regular, at a rate 90 to 100. The neck veins were not distended. The lungs were clear. The abdomen was markedly distended, and there was shifting dullness in the flanks. Large veins could be seen in the anterior abdominal wall, but there was no hum audible at the umbilicus. A tender liver edge could be felt five fingerbreadths below the right costal margin and about the same distance below the ensiform in the midline; its upper border was percussed at the fourth interspace. The spleen could not be felt. Rectal examination showed external hemorrhoids and questionable enlargement of the left lobe of the prostate.

The blood pressure was 110 systolic, 85 diastolic. The temperature was 98.8°F., pulse 100, respirations 25.

Laboratory determinations showed a hemoglobin of 15.5 gm. and a red-cell count of 4,250,000. The white-cell count was 10,500, with 72 per cent polymorphonuclears, 18 per cent lymphocytes and 10 per cent monocytes; the smear was not remarkable. The hematocrit was 56 per cent. A single urine examination showed a specific gravity of 1.003 and gave a + test for albumin; there was no sugar or bile. The sediment showed 3 red cells and rare white and epithelial cells per high-power field. A stool was tan colored and contained bile; the guaiac test was negative. The serum nonprotein nitrogen was 82 mg. per 100 cc., and the prothrombin time 41 seconds (normal, 22 seconds). The liver function test showed 95 per cent retention of the dye in the serum. The serum protein was 7.8 gm., the albumin 4.5 gm., and the globulin 3.3 gm. per 100 cc. An electrocardiogram was interpreted as follows: normal rhythm, rate 85; low voltage of the QRS complexes; low T waves, slightly diphasic in Leads 1 and 2, having the appearance of digitalis effect; no abnormal axis deviation; P waves and PR intervals normal; normal R₄ and a rather low T₄.

During the six days in the hospital his many discomforts rapidly increased and his strength diminished. Chloral hydrate, Nembutal and Empirin Compound failed to give relief. A single dose of 1/6 gr. of morphine made him drowsy for twenty-four hours. Two abdominal paracenteses yielded less than a liter of fluid each. The specific gravity was 1.009. It contained 160 white cells (110 polymorphonuclears, 30 lymphocytes and 20 mono-

cytes) and 880 red cells per cubic millimeter. The sediment was negative for tumor cells.

On the sixth hospital night the house officer was called at 3:30 a.m. He found the patient dead, with large amounts of dark-red blood still oozing from the nose and mouth.

DIFFERENTIAL DIAGNOSIS

DR. ALFRED KRANES: It seems unlikely that the fall occurring nine months before death had much to do with this patient's illness, and I shall dismiss it from consideration, except to say that five weeks is a little long to be incapacitated from work because of a sprained knee and ankle. It raises the question whether some serious underlying disease was not already present, to which attention was directed by the fall. The appearance of the rash shortly thereafter is probably coincidental. Why a purpuric rash should itch puzzles me, for it has always been my impression that pruritus does not occur with purpura. Since clinical jaundice was noticed shortly thereafter, a possible explanation for the itching may have been the jaundice, rather than the rash to which it was attributed.

I regret that so little information is given concerning the first physical examination, which mentions only "probable ascites and an icteric tint to the scleras." Presumably the purpuric rash was present at that time. What would interest me more is a statement about the liver and spleen, since the former was easily felt on subsequent examination, and it would be important to know whether the apparent rapid increase in size was actually true. Since it is not mentioned, I am going to assume that the liver was not felt initially, and that it did rapidly increase in size, becoming tender in the process. The laboratory data, except for the slight rise in the icteric index, are normal at this examination.

The past history is of interest because of the attack of jaundice at twenty. Presumably this was catarrhal jaundice, which is the commonest type at this age and which may be related to his terminal illness, obviously involving the liver. Most cases of catarrhal jaundice clear up, leaving no residual liver damage, but a small percentage may either develop subacute yellow atrophy or show evidence of cirrhosis years later.

The problem is a very interesting one, and I am not at all sure that I can adequately explain it. The opening sentence of the history immediately suggests the possibility of some sort of heart disease, for which he was apparently treated with Salyrgan and digitalis. Furthermore it is implied that this resulted in lessening of the edema of his legs. Certainly the presence of an enlarged ten-

der liver, ascites and edema of the legs is consistent with cardiac failure. However, I can find little in this story to support such a diagnosis. Although dyspnea is stated as one of his chief complaints, there is no further mention of it anywhere in the history. Furthermore there was no clinical evidence of pulmonary congestion, or of increased venous pressure except in the abdomen. If the large tender liver was due to cardiac failure, the neck veins should also have been distended. Nor did the examination of the heart itself show any evidence of disease, although the absence of enlargement clinically is not too reliable. The patient was probably too ill for x-ray examination. As for the electrocardiogram, all it reveals to me is a digitalis effect and the type of tracing one might expect in any debilitated patient without heart disease. I should like to ask Dr. Bland for his interpretation.

DR. EDWARD F. BLAND: We thought that there was no evidence of intrinsic disease of the cardiovascular system. The electrocardiogram was taken because of interest in the possible presence of heart disease secondary to the thoracic deformity.

DR. KRANES: I think we can therefore safely dismiss heart disease from consideration. The past history, the presence of jaundice and ascites, evidence of collateral circulation in the abdominal wall, an easily palpable liver, the terminal hematemesis and the clinical effect of a small dose of morphine—all these factors are strong evidence in favor of some sort of intrinsic liver disease, probably cirrhosis, which I am inclined to believe was present. What type of cirrhosis is difficult to say without more history, but I favor a toxic cirrhosis despite the absence of known toxic factors. It would be of some interest to know whether he took any drugs such as cinchophen for relief of the pains in his legs following his fall, or whether he received injections of gold salts for what may have been diagnosed as an arthritis. Presumably not. There is no evidence that any arsenical drugs had been administered. The question of drug idiosyncrasy must be further emphasized because of the presence of the purpuric rash, which we have not explained, and to which I shall return in a moment. Despite the evidence in favor of cirrhosis there are a number of disturbing factors that argue against it.

In the first place his illness progressed much more rapidly than the usual case of cirrhosis, in the absence of any signs of subacute yellow atrophy. Furthermore, I cannot understand why the liver should have increased so rapidly in size, if that observation was correct. To be sure, estimates of liver size are likely to be quite erroneous, but this

was a comparative observation made at different times and is therefore likely to be somewhat more reliable. Then too, cirrhotic livers are not likely to be as tender as this one was. A tender liver is usually a congested one, or one that contains a malignant tumor. Also, the absence of splenomegaly is disturbing in a patient who has cirrhosis. Finally, I cannot see how a diagnosis of cirrhosis of the liver explains the most prominent clinical feature of his illness—the purpura. And I might add that I can find no other satisfactory explanation for it. A bleeding tendency does occur in severe liver disease with an increased prothrombin time; but I have never heard of its being confined so exclusively and so extensively to the skin, as in this case. The skin manifestations of a prolonged prothrombin time are likely to be diffusely ecchymotic rather than discretely purpuric. The fact that the purpura preceded by months the clinical evidence of liver disease need not disturb us, for I have seen patients admitted to the Emergency Ward with repeated epistaxes, only to turn up a year later with obvious cirrhosis. However, I find it difficult to believe that the purpura in this patient was in any way related to his liver disease.

I do not know what was the cause of the skin lesions. There is no evidence whatsoever pointing toward the usual causes of purpura, such as a primary blood dyscrasia and drug ingestion. The possibility of scurvy occurred to me in view of the perifollicular hemorrhages and the pains in the legs. Although he was extensively treated with vitamins A, B, D and K, there is no mention of his having received any vitamin C. Scurvy is an unusual disease these days, but even so it seems improbable that it was missed. Might I ask about his dietary history?

DR. BLAND: The patient had been on an adequate diet.

DR. KRANES: That, I think, adequately disposes of the question of scurvy. Since I can find no satisfactory explanation for it, I shall have to call it purpura of undetermined etiology.

For the reasons that have already been stated, cirrhosis does not completely explain this picture, and it becomes necessary to consider whether any additional factors were present. The facts that the disease progressed fairly rapidly and that the liver increased in size while becoming tender immediately raise the question of cancer. If this patient had malignant disease I can see no way of making the diagnosis without further study, which was precluded because of his condition. Metastatic carcinoma could explain much of it, but without any anemia or obvious primary focus it remains

only a possibility. Lymphoma of the liver is not only quite uncommon without other evidences of the disease, but a fever usually accompanies it, which was not present in this case. Another possibility is hepatoma, for which we seem to have the proper background—a pre-existing cirrhosis. Again one can only mention the possibility.

A rare possibility, which might be mentioned in an attempt to explain the rash, is acute disseminated lupus erythematosus, the skin lesions of which may be purpuric. It would explain the rash, the joint and abdominal pains, the ascites and the terminal renal failure without hypertension. However, it rarely occurs in men and, so far as I know, never involves the liver. We can therefore dismiss it. I do not believe there was any primary renal disease, despite the urinary findings and nitrogen retention. These can be attributed to the fact that there was terminal renal failure in an otherwise very ill patient.

In conclusion, my belief is that this patient had cirrhosis of the liver, but since this does not adequately explain the whole picture, I raise the question whether or not something else was present, such as a hepatoma.

DR. EUGENE R. SULLIVAN: Dr. Bland, you saw this case: would you care to add to the discussion?

DR. BLAND: It was extremely difficult to get an adequate history from this patient. In spite of the marked thoracic deformity of long standing we were convinced that the heart action was entirely competent. We agreed that cirrhosis of the liver was most likely; but the rather rapid progression in the size of the organ, its tenderness and the high degree of abdominal venous stasis developing in the course of a month suggested to us, as it has to Dr. Kranes, some additional complication, such as cancer.

I think it is important to emphasize the profound narcosis that a small dose of morphine produced in this patient. This in turn lent additional support to the diagnosis of extensive hepatic disease.

DR. S. PETER SARRIS: Should not hepatic-vein thrombosis be considered? That would explain the enlargement of the liver, apparently increasing under observation, and the fact that the patient failed more quickly than most of those with cirrhosis.

DR. KRANES: In thinking over this problem I had considered that, but because of its rarity did not mention it. However, it is distinctly possible and would explain some of the atypical features.

CLINICAL DIAGNOSES

Cirrhosis of liver.
 Subacute hepatitis.
 Abdominal cancer?
 Terminal hemorrhage, from esophageal or possibly gastric varices.

DR. KRANES'S DIAGNOSES

Cirrhosis of liver.
 Hepatoma?
 Purpura (? cause).

ANATOMICAL DIAGNOSES

Primary liver-cell carcinoma (hepatoma), with extension into and obstruction of inferior vena cava.
 Cirrhosis of liver, toxic.
 Ascites.
 Icterus, slight.
 Gastric erosions, multiple, small, mucosal.
 Duodenal ulcer.
 Arteriosclerosis, moderate: aortic, coronary and peripheral.
 Pulmonary tuberculosis, healed, localized: apical.
 Kyphosis: thoracic.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: I happened to prepare the clinical abstract of this case personally and, as I did so, amused myself by attempting to guess how it would be discussed. I expected that the discussor would briefly consider and quickly eliminate kyphoscoliotic heart disease. I then expected him to take up the confusing data regarding liver insufficiency—on the one hand, the low prothrombin value, the bromsulfalein retention and the terminal gastric hemorrhage, and on the other hand, the absence of demonstrable esophageal varices, of splenomegaly, of leukopenia, of lowering of the serum protein or of reversal of the albumin globulin ratio. I expected that he would reach the conclusion that cirrhosis of the liver alone could not explain the picture, and that he would advocate either malignant tumor or mechanical obstruction of the vena cava as the underlying factor. Dr. Kranes has reached the correct diagnosis by a slightly different route.

I should like to read two clinical notes from the hospital record, written before the patient died. The first is by Dr. Bland:

My first impression is that the chief difficulties are portal obstruction and hepatic insufficiency of rather acute onset and probably complicating chronic asymp-

tomatic liver disease. The normal serum protein and prothrombin determinations are disturbing.

The thoracic deformity is a further handicap and has probably resulted in some strain on the right heart, but I am doubtful that cor pulmonale or inflow stasis to the heart is the important feature behind the jaundice, dermatitis, large liver, ascites and dilated veins below the diaphragm.

I cannot feel the spleen; I hear no umbilical hum, and the heart on physical examination does not seem to be enlarged. The pulmonic second sound is not suspiciously loud, and there is no gallop. I cannot be certain of the cervical veins, but those on the dorsum of the hand seem slightly swollen above the level of the heart (? secondary to abdominal tension).

Dr. Chester M. Jones saw the patient in consultation and commented as follows:

I cannot make a diagnosis. There is obvious embarrassment of the venous return through the vena cava. It is not possible to connect adequately the edema and the ascites with hepatic failure. If the ascites is purely mechanical and due only to intrahepatic disease, the absence of anemia, varices, splenomegaly and lowered serum albumin are unusual. I think that caval pressure must be considered and that carcinoma must be ruled out. Regardless of the underlying diagnosis, everything is exaggerated by his deformity. I believe he has an incurable disease and advise peritoneoscopy as the best means of establishing a diagnosis.

On post-mortem examination, we found a cirrhotic liver with a large nodule of hepatoma in the right lobe. This had spread, as it so often does, in the form of a tumor thrombus infiltrating along the hepatic venous radicles. A thrombus of tumor protruded from the main hepatic vein and was continuous with a similar mass that almost completely obstructed the inferior vena cava for its upper 7 or 8 cm. It stopped just short of the mouth of the cava at its junction with the right auricle. The cirrhosis was an old inactive one of the toxic type. The spleen was not enlarged, weighing only 170 gm., and there were no esophageal varices. The final hematemeses, which caused death, probably resulted in part from an extremely severe erosive gastritis with some fifty small, shallow, hemorrhagic erosions, mostly along the greater curvature, and in part from an acute duodenal ulcer about 2 cm. in diameter.

The heart was slightly enlarged but showed no evidence of cor pulmonale. The kidneys were large but showed only severe passive congestion, undoubtedly secondary to the caval obstruction. There was healed apical pulmonary tuberculosis, and one very large, densely calcified bronchial lymph node was found. There was nothing to explain the skin lesions, unless it was the liver disease.

PASS THE AMMUNITION

We are reminded every so often that where there is no vision the people perish. Our vision has occasionally become very dim even if it has never entirely faded, and this has usually occurred when the present has seemed most fruitful and the future most promising. It is only when we are combating adversity that we realize the sweetness of its uses, and then, for a time, the veil is lifted from our eyes.

A year ago at Christmas time we had embarked on a common enterprise, each of us sharing the hopes of victory and risking the dangers of defeat. We were confused and uncertain then, fearful of our weaknesses and ignorant of our strength. We knew what we had been spared

of the miseries of other peoples, but we did not know how long we might be spared them, or what else the future might contain. We knew only that a year of giving ground was in store for us—a year of sparring for time before we had strength to strike back.

Some of our weaknesses have been uncovered, and we know now that we have strength and courage and initiative in spite of the soft years that are behind us. We have put a girdle around the earth, if not, like Puck, in forty minutes; our youths are standing to their arms by Greenland's icy mountains and on Africa's golden sands. They are, to borrow further from the same literary source, basing their activities on the coral strands of India; and the heathen who, in his blindness has bowed down to wood and stone, bows also before the fire of our guns of destiny.

We are celebrating at this season the great pageant of Christianity, but it is as militant Christians that we are observing it. As we go forth to war, the Son of God goes with us. This year we will praise the Lord, as usual, but we will also pass the ammunition.

POLIOMYELITIS RESEARCH

DURING the last few years, much has been added to our scant understanding of an age-old disease, poliomyelitis. The virus, for example, has been isolated from the stools of patients and contacts and has been found both in sewage and in flies collected in epidemic areas. It is now thought, moreover, that the common portal of entry in man may be the alimentary tract, as well as, or perhaps in place of, the long-recognized route through the olfactory mucous membrane. A study of the transmission of the virus along axons and an evaluation of the various factors affecting its progress to the central nervous system are being actively prosecuted. The whole subject of neurotropic viruses and of their action on the body is, indeed, in the forefront of medical research today.

Not the least significant in this advance is the

work of Howe and Bodian.* They have shown that the virus of poliomyelitis is highly specific for the neuron and, in the peripheral nerves, migrates along the axons themselves rather than within the sheaths of the nerves. The rate of progress, according to their estimate, is 2 or 3 mm. per hour. Moreover, if the direct axonal pathway is not open, the virus may progress centrally through distant autonomic ganglions. How the virus penetrates the epithelium is still obscure, as is the problem why some intestinal contents tolerate the virus and some do not. In a rhesus (monkey), for example, the intestinal secretions are unfavorable for effective survival of the virus, whereas in a chimpanzee and in a cynomolgus (monkey), it is regularly found in the stools. These and other problems of host susceptibility are still matters for future research.

A most striking finding is their demonstration that susceptible nerve cells may become refractory during the time their injured axons are being reconstituted. The nature of this reaction is unknown, but it may depend on the chemical constitution of the cell protoplasm. The cells showing refractoriness to poliomyelitis still appear to be alive and capable of carrying on their normal functions. Such findings may well lead to changes in the treatment of the disease in human beings.

Other investigations by Howe and Bodian deal with the humoral mechanisms tending to protect the host at the portal of entry of the virus, the variability of susceptibility in different parts of the central nervous system, the local immunity of any one part afforded by a previous attack and the general problem of the control of poliomyelitis. On the last point, the following is quoted from the final paragraph of their summary:

At the present time the control of poliomyelitis can be attempted along three lines, namely, preventing the virus from reaching the susceptible individual or, failing this, arresting the progress of the virus before it has reached the central nervous system or, lastly, limiting the spread of virus within the central nervous system. The development of these approaches is proceeding in a somewhat more satisfactory fashion with

the acquisition of newer knowledge concerning the dissemination of virus, the portals of entry, and the forces which make for resistance in the organism. It seems not unlikely that the next few years will see more practical fruition of these efforts.

OBITUARY

FRANCIS SEDGWICK WATSON†

1853–1942

It is the difficult duty of the writer of such a notice as this to try to give a word picture of a remarkably brilliant, handsome and versatile man, a character unique in the writer's experience, and most lovable. He was an excellent surgeon, a remarkable linguist, a most loyal friend, a faithful servant of the Boston City Hospital and the Harvard Medical School, a man of high ideals and fine sensibility. He was vibrant with the joy of life, and a most entertaining companion, a thorough sportsman and lover of the outdoors. Of his many summers spent on the Saguenay, he has left a most delightful account in that rare book, *A Bundle of Memories*, which it has been my privilege to read. In whatever he undertook, his ideals were of the highest. As one of his juniors on the staff of the Boston City Hospital I can give personal testimony to his kindness and helpfulness to the younger and less experienced members of the staff, to his readiness in encouragement and his frankness in criticism.

He was born in Milton, Massachusetts, on May 31, 1853, the son of Robert Sedgwick and Mary Hathaway Watson. He graduated from Harvard College in 1875, and from the Harvard Medical School in 1879. He was surgical intern at the Massachusetts General Hospital in 1878, his colleague being Dr. John B. Wheeler, that sterling surgeon of Burlington, Vermont, with whom he maintained a delightful and intimate friendship the whole of his long life. Their deaths came within a few months of each other.

The leading surgeons of the hospital at that time were Dr. Henry J. Bigelow, Dr. Richard M. Hodges, and Dr. C. B. Porter, all of whom he greatly admired, and of whom he has written delightfully in his *Bundle of Memories*. He had the greatest admiration for Dr. Bigelow, and being like him, a tall, handsome and brilliant man, with a very marked personality, he reminded his associates of that famous surgeon in his manner and ways of speaking, especially before the students. His real instinct for showmanship helped him to

*Howe, H. A., and Bodian, D. *Neural Mechanisms in Poliomyelitis*. 234 pp. New York: The Commonwealth Fund, 1942.

†Read at the annual meeting of the Boston Surgical Society, Boston, December 7, 1942.

emphasize the points of his lectures and clinics, and his brilliant wit made them most entertaining.

After leaving the hospital, he studied in Europe for two years. Of these years he writes, "Those were glorious years, those years we passed in Europe, putting the finishing touches to our medical education, and while yet free from serious care and responsibilities." He studied at Vienna, after two months spent in a German family in Dresden in order to learn the language, and in Strasbourg he worked in the laboratories of Waldeyer and von Recklinghausen. On his vacations, he traveled extensively in Italy, Spain, France and North Africa: His description of his travels reveals a keen appreciation of the art, architecture, music and life in these countries as seen by a young, enthusiastic and brilliant observer. I do not know of any writing on travel more interesting and amusing than this part of his *Bundle of Memories*.

On his return to this country, he started practice in Boston, beginning by doing a dispensary district. He was surgeon for genitourinary diseases at the Boston Dispensary, and surgeon to out-patients at the Children's, Boston City and Carney hospitals. He was instructor and lecturer on minor surgery and genitourinary diseases at the Harvard Medical School. In 1894, he became visiting surgeon at the Boston City Hospital, and in 1896 was the head of the Genitourinary Department at Harvard, and was president of the American Society of Genito-Urinary Surgeons, presiding at the triennial meeting in Washington. In 1890, he had been a delegate from the American Association of Andrology to the International Medical Association in Berlin. In 1897, he was invited by the Russian Committee of the International Medical Congress, which met in Moscow, to be one of the honorary presidents of the Congress of the Society of Surgery. He attended the meeting, and astonished and delighted the natives by giving his address in Russian, which, needless to say, was a result of much study and a *tour de force* of memory. Of this he writes:

The president called on me to speak and I began in French, saying that I would very much like to respond to our hosts in their own language, and that if they would be indulgent, I would make the attempt to do so. Then I sailed in. With the first words a low murmur arose from the Russians. I at once felt that I had placed the accent on the wrong syllable somewhere in the phrase, and broke into a cold perspiration as the vision of the long journey to Siberia, which was called into being by my heated imagination, arose before me. I felt persuaded that I must have said "to hell with the Tsar," or some equally damning words, and braced myself to meet the worst. Then I noticed that the Russians were advancing toward me,

holding their champagne glasses in their hands, and smiling encouragement. Being thus relieved as to my fate, I went on with the following few words.

These few words proved to be a delightful message of thanks to the Russians for their warm hospitality, and a statement of the pleasant memories he should carry home, and wishes for their good fortune, happiness and success. The enthusiasm of the Russians for his address passed all bounds, and, therefore, many healths were drunk, and he had to pretend to drink them in order to avoid direful consequences.

In 1908 with Dr. John H. Cunningham, Jr., he published a complete textbook on diseases of the genitourinary system, which has remained a standard treatise to this day.

Besides the local and national societies, he was a member of the International Surgical Society, the Urological Society of Germany and that of Russia, a corresponding member of the Surgical Society of Moscow and an active member of L'Association Française d'Urologie (vice-president in 1911). In 1921 he was elected honorary president of Société Internationale d'Urologie.

In 1906, he resigned as surgeon-in-chief at the Boston City Hospital and lecturer at the Harvard Medical School after twenty-five and thirty years, respectively, of service. He was a charter member of the Tavern Club, and contributed a brilliant play which he wrote and staged among many other contributions to its proceedings.

He was married at Boston, June 16, 1886, to Mary Perkins, who died at Boston, September 19, 1917. In October, 1918, he married Genevieve Walker. He had one daughter, who died in infancy, by his first marriage.

In his surgery, he was forward-looking and courageous. He lived through the time when prostatectomy became a recognized operation, and did much, by example and writing, to help on the adoption of this operation, which has been so great a boon to many sufferers.

In 1888, Dr. Watson presented in monograph, the first classification of the gross pathology of the prostate and formulated the proper surgical procedures to deal with the various types. He emphasized the advantage of attack of certain intravesical growths suprapubically and smaller hypertrophies, both sclerotic and malignant, through the perineum. These principles remain the same today, and it is generally recognized that it was his foresight that outlined the surgical principles now employed.

He was also a pioneer in the electrical destruction of tumors of the bladder, for which he invented an instrument to be employed through suprapubic exposure, as well as the destruction of prostatic hypertrophy with a galvanocautery instrument of his own invention, which was employed by intraurethral manipulation, a procedure that antedated those of Friedenborg and Bottini.

In the New England Surgical Society, who of the members can forget his brilliant addresses at two meetings, in Portland, Maine, and St. Albans, Vermont, where his wit flashed like a comet across the level of our scientific monotony? The dinner at Vermont was held on one of the Lake Champlain steamers, and the combination of the good dinner, the lovely lake and Frank Watson's address cannot soon be forgotten.

I cannot close this notice of a beloved, loyal and brilliant friend without saying a word about his admiration and appreciation of his older friends and colleagues, such as Drs. David Cheever, Ned Bradford and George W. Gay, of whom he wrote most charmingly in his *Memories*. Loyalty and kindness were his chief characteristics, and there was not a mean, jealous or unkind drop of blood in his body. He differed from most of us in his facility and clearness in the expression of his thoughts and feelings, and these thoughts and feelings to the last were those of a good friend and gallant gentleman.

F. B. L.

MEDICAL EPONYM

SKODAIC TYMPANY

This is described by Dr. Joseph Skoda (1805-1881), chief physician of the Vienna General Hospital, in his book, *Abhandlung über Perkussion und Auskultation* [*Treatise on Percussion and Auscultation*] (Vienna, 1839). A portion of the translation from the third edition (Vienna, 1844) follows:

It would seem contrary to the laws of physics that a lung containing a small amount of air should give a tympanitic note, whereas the same lung with an increased air content is not tympanitic. The fact, however, is well established and is borne out not only by experiments made on the cadaver, which will be referred to later, but by the constant finding that in the presence of exudate in the thoracic cavity, which entirely compresses the lower part of the lung and markedly reduces the volume of the upper lobe, the percussion note is distinctly tympanitic over the upper part of the thorax.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

SECRETARY'S OFFICE

Dr. Frank H. Lahey, chairman of the Directing Board of the Procurement and Assignment Service, has requested the publication of the following statement, dated December 16.

MICHAEL A. TIGHE, *Secretary*

* * *

It is of the utmost importance that the Procurement and Assignment Service for Physicians, Dentists and Veterinarians, immediately has the name of any doctor who really is willing to be dislocated for service, either in industry or in overpopulated areas, and who has not been declared essential to his present locality. This is necessary if the medical profession is to be able to meet these needs adequately and promptly. We urgently request that any physician over the age of forty-five who wishes to participate in the war effort send in his name to the state chairman for the Procurement and Assignment Service in his state.

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1941

TOXEMIA AND ECLAMPSIA (*Concluded*)

Of the remaining 19 cases of toxemia and eclampsia, 6 patients died undelivered and 13 were delivered normally or by vaginal operation.

The first of the 6 undelivered patients was a woman in her second pregnancy on whom a diagnosis of essential hypertension had been made before pregnancy, since her systolic blood pressure consistently ranged from 160 to 180. Following an attack of abdominal pain the blood pressure rose to 290 systolic, 140 diastolic and she was sent immediately to the hospital. After a convulsion she went into coma and died undelivered. Autopsy revealed scattered hemorrhages throughout the viscera, cerebral hemorrhage and acute peripheral necrosis of the liver. This patient should not have been allowed to become pregnant.

The second patient, a multipara who had had no prenatal care, was known to have chronic hypertension. She was not seen until the seventh month, at which time she had a convulsion. She was immediately hospitalized, being comatose on arrival, and died undelivered. It is probable that

this patient should not have been allowed to become pregnant; however, intelligent prenatal care might have averted this disaster. Cerebral hemorrhage was probably the immediate cause of death.

The third case was that of a patient who had not seen a physician throughout her pregnancy, was seized with convulsions when at term and was hospitalized. She was unconscious on entry; the blood pressure was 186 systolic, 114 diastolic, there was albumin in the urine, and the fetal heart was inaudible. The patient died undelivered. Fortunately an autopsy was performed, which revealed eclampsia and acute passive congestion of the kidneys. This was probably an unnecessary death. It is shocking that no medical advice was sought or given during pregnancy until eclampsia itself was present.

The fourth patient, a primipara who had had no prenatal care, was admitted to the hospital in active convulsions, which were followed by coma. Conservative treatment alone was employed; death occurred twenty-four hours after admission. The patient was undelivered, but a stillborn fetus was obtained by post-mortem cesarean section. Autopsy showed focal necrosis of the liver, fatty degeneration of the heart and cardiac dilatation. There is little to be said about this case. Present-day knowledge would lead one to suppose that intelligent and adequate prenatal care would have averted this catastrophe. Certainly eclamptic symptoms existed a few weeks before the convulsions occurred and, if recognized, might have responded to treatment directed toward the removal of the fetus before the eclamptic seizures occurred.

The fifth patient was a primipara who had a normal pregnancy until she reached the twenty-second week, at which time she was "taken ill" while at the beach and advised to return to her own home. Shortly after reaching home she had a convulsion and was seen by her physician, who found a blood pressure of 200 systolic, 140 diastolic, considerable edema and a large trace of albumin in the urine. She was immediately sent to the hospital, where labor started spontaneously the day after entry, but went steadily downhill and died undelivered. This was a very early case of eclampsia. It is possible, although the history does not suggest it, that some chronic kidney involvement was behind this. No attempt to operate was made, and from this standpoint the treatment can in no way be criticized.

The history of the sixth patient is inadequate. At eight and a half months she apparently developed acute eclampsia, and the baby was not delivered. Autopsy revealed fulminating toxemia and central necrosis of the liver.

The 13 remaining patients were delivered normally or by vaginal operation. The first patient was a twenty-three-year-old primipara who had had a nephrectomy several years previously and who, at eight and a half months, had a blood pressure of 160 systolic, 100 diastolic, and a large trace of albumin in the urine. She was hospitalized, and an attempt at induction of labor by packing the cervix was unsuccessful. The vagina, however, was packed with gauze the following day, and labor was initiated. The next day she had a convulsion, at which time she was said to be fully dilated. Delivery was accomplished by forceps, but the patient continued to have convulsions and died thirty-six hours post partum. It is possible that delivery should have been considered sooner; furthermore, the practice of packing of the cervix to induce labor is antiquated. The existence of only one kidney was undoubtedly contributory to the toxemia that resulted fatally.

The second patient, whose first baby had been delivered by cesarean section, had had inadequate prenatal care. On the twenty-first week she was presumably all right, but on her next visit, five weeks later, she had an increased blood pressure with albuminuria and edema. She was immediately hospitalized, but conservative treatment did not achieve any benefit. The patient went into convulsions; labor, which was normal, was induced by rupture of the membranes and was followed by delivery of a macerated fetus. The patient did not regain consciousness and died shortly after delivery. The treatment in this case cannot be criticized. The patient herself was at least partly to blame for not making regular prenatal visits.

The third patient, a thirty-six-year-old primipara on whom a diagnosis of essential hypertension had previously been made, did not consult her physician until approximately six months pregnant, at which time she had a systolic blood pressure of 260, a urine filled with casts and a +++ test for albumin. Instead of being immediately hospitalized, she was sent home to bed. Two weeks later she was sent to the hospital. Labor began spontaneously the day after entry, and she delivered herself of a macerated fetus. She apparently had a convulsion during delivery, which resulted in a cerebral hemorrhage; she did not recover consciousness and died a few hours later. It is questionable whether this patient should have ever been allowed to become pregnant, and in the event of pregnancy, abortion should have been advised at her first prenatal visit. She should have been hospitalized when first seen; and an early delivery when the symptoms did not abate might have prevented this fatality.

The fourth patient was a woman in her second pregnancy who was given adequate prenatal care from the beginning of pregnancy; she was classified as having a Grade I pre-eclampsia. Before delivery the blood pressure was 160 systolic, 98 diastolic. She went to term and was delivered normally, convalescence being uneventful until the thirteenth post-partum day, when she had convulsions, which were followed by a cerebral hemorrhage. Death occurred three days later, and autopsy revealed cerebral thrombosis and hemorrhage and chronic rheumatic heart disease; there was no reference to pathologic lesions of the kidneys. In no way can the handling of this case be criticized.

The fifth patient was a primipara who, at eight and a half months, had definite toxemia associated with separation of the placenta. A normal delivery was followed by two convulsions two days afterward, from which the patient did not recover. There was absolute suppression of urine post partum. The treatment of anuria associated with toxic separation of the placenta by decapsulation of the kidney has often proved successful, and its use might have done some good in this case.

The sixth patient was a multipara who was seen only once during her pregnancy, when just short of seven months. Ten days afterward she had a cold, with a temperature of 104°F. Labor started spontaneously the following day, and a premature infant was delivered. That evening the patient became desperately ill and was sent to the hospital, where she died shortly after entry. Autopsy revealed toxemia of pregnancy. This history is so sketchy that it is difficult to make the information given to the investigator correlate with the facts. The autopsy, however, showed that toxemia was the real cause of this fatality, although the attending physician made no mention of increased blood pressure or albuminuria. This patient had neither adequate prenatal care nor intelligent care after she had seen her physician.

The seventh patient, a primipara who was said to have a large trace of albumin and a systolic blood pressure of 140 at five months, was not seen again for two weeks, at which time the physician was summoned to her home and found her complaining of headache and blindness, with a systolic blood pressure of 200 and a urine solid with albumin. The following day she delivered herself spontaneously of a stillborn infant. Acute anuria developed, and death occurred six days afterward. This patient was not given intelligent or hardly humane treatment.

The eighth case was that of a primipara who was known to have had hypertension and albuminuria and who had had excellent prenatal care. The only criticism of the case is that the patient

was allowed to go into spontaneous labor at term with a systolic blood pressure of 200 and without being hospitalized before delivery. Convulsive seizures occurred after delivery, and the patient died of anuria fifteen days post partum. This is a case of post-partum eclampsia that undoubtedly was the result of hypertensive kidneys. Had this patient been delivered at eight months, when the baby was viable, the fatality in all probability would not have occurred.

The ninth case was that of a patient who had been toxic during pregnancy two years previously and had been delivered of a stillborn infant. She was not seen until the seventh month of her second pregnancy, at which time she was said to have been normal. When near term she became irrational and the systolic blood pressure rose to 160, with marked edema and moderate albuminuria. The toxemia was accompanied by jaundice. Six hours after the induction of labor by artificial rupture of the membranes a stillborn fetus was delivered, and the patient expired shortly after delivery from circulatory collapse, which may well have been due to the toxic myocarditis that is occasionally associated with severe toxemia. The jaundice suggests liver involvement. This patient was not given adequate prenatal care, especially in view of her previous toxemia.

The tenth patient, a primipara who had had no prenatal care, gave an entirely negative history up to the time of labor, which started prematurely at six and a half months; she was sent to the hospital, and delivery was accomplished soon after entry. A convulsion occurred immediately after delivery, and anuria was followed by death one week later. Intelligent prenatal care would have undoubtedly averted this disaster.

The eleventh patient was a primipara who had had moderately intelligent prenatal care and was said to have been normal until the end of the seventh month, when the blood pressure was 160 systolic, 100 diastolic. One week later the blood pressure returned to normal, but three weeks before the onset of labor it again became elevated. The patient was not seen again until she had a convulsion, at which time the blood pressure was 190 systolic, 120 diastolic. A stillborn child was delivered not long after hospital entry. Anuria developed immediately after delivery. Probably a cerebral hemorrhage was the immediate cause of death, which occurred twelve hours after delivery. Of course, this patient should have been seen more frequently at the end of pregnancy. It is difficult to understand how any physician could let three weeks go by without seeing a patient whose systolic blood pressure was 190.

The twelfth patient, a primipara who had had adequate prenatal care, was sent to the hospital at the beginning of the tenth month because of a systolic blood pressure elevated to 180, edema and considerable albuminuria. The day after entry she had two convulsions; labor started spontaneously, and a stillborn infant was delivered by low forceps. The patient was comatose after delivery and died twelve hours later. Autopsy was performed, but unfortunately the report could not be found. In this case, delivery should have been considered earlier.

The history of the thirteenth and final case is inadequate; apparently toxemia proved fatal in a patient who was delivered normally at term.

In the entire series of 27 cases, six autopsies were performed.

In reviewing these cases of toxemia and eclampsia, it is extremely gratifying to find that in none was *accouchement forcé* resorted to. In only one case can the operative management be criticized, this being the one in which cervical packing was attempted. It is deplorable that so many of these cases were treated by cesarean section after eclampsia had established itself, since it is almost an axiom that an eclamptic seizure contraindicates section. It is also deplorable that some of these patients with eclampsia had no prenatal care, and one cannot help but believe that some of them at least might have been saved had they been seen routinely during pregnancy. The number of patients who died undelivered is noteworthy. Eclampsia may certainly be a rapidly fatal disease.

The two patients on whom nephrectomy had been performed years previously illustrate the potential seriousness of pregnancy in a patient with one kidney. Such patients should be watched more carefully than the normal pregnant woman, and it might be well, for the purpose of saving added work on the one remaining kidney, to anticipate labor by the proper method of emptying the uterus after viability.

The tabulation for 1941 shows an increase of 2 in the deaths from toxemia and eclampsia as compared with that for 1940. An analysis of these deaths in 1941 clearly shows that many of them were preventable.

A CORRECTION

I wish to correct a statement made in the report to the Council of the Massachusetts Medical Society of my survey of the state-aided cancer clinics, which appeared in the November 12 issue of the *Journal*.

When I visited the clinic at the Boston Dispensary I was told they did not have facilities for treatment with a high-voltage x-ray machine. Mr. Frank E. Wing, the director, now tells me I was misinformed and that a 200,000-volt machine for patients requiring that form of treatment was installed several years ago.

CHANNING C. SIMMONS, M.D.

DEATHS

BRIGGS—CHARLES A. BRIGGS, M.D., of Assonet, died December 14. He was in his eightieth year.

Dr. Briggs received his degree from the Long Island College of Medicine in 1889. He was appointed school physician soon after he went to Assonet to practice. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

His widow and a daughter survive him.

DIXON—ROBERT B. DIXON, M.D., of Boston, died December 16. He was in his eighty-seventh year.

Born in Damariscotta, Maine, he received his degree from Harvard Medical School in 1879. For twelve years he was physician at the Boston Dispensary and was commissioner on the Massachusetts Nautical Training School. He had been a director of the Robert B. Brigham Hospital since it was founded. He was a fellow of the Massachusetts Medical Society and the American Medical Association. For a number of years he was associated with the Medical Department of the Employers Liability Assurance Corporation.

Three daughters and five grandchildren survive him.

OLEF—ISADORE OLEF, M.D., of Dorchester, died December 16. He was in his forty-sixth year.

Dr. Olef received his degree from Harvard Medical School in 1926 and at the time of his death was assistant professor of medicine at Tufts College Medical School. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

His widow and two daughters survive him.

WAR ACTIVITIES

CIVILIAN DEFENSE

LESSONS FROM BRITISH EXPERIENCE IN CIVIL DEFENSE

The following circular (Medical Series No. 20) was recently sent to all regional directors and regional medical officers by Dr. George H. Baehr, chief medical officer, United States Office of Civilian Defense:

Three years of British experience with air raids have significantly modified earlier concepts regarding the field casualty services. The following observations made on a recent inspection of emergency medical facilities in England and Scotland are forwarded for your information and for transmission through state chiefs to local chiefs of Emergency Medical Services.

(1) Heavy raids occur invariably at night; heavier high-explosive bombs and land mines are now being employed, up to 2000 kg., with much greater destructive ef-

fects. Incendiary bombs are used in much larger numbers, and fire is now the most serious hazard. Daylight raids are usually hit-and-run affairs in which solitary planes participate.

(2) In large cities the field casualty services may handle 2500 to 3500 casualties during a night raid. All serious casualties are moved directly to hospitals, never to first-aid posts. Heavy raids are apt to be repeated on subsequent nights when the protective forces are exhausted.

(3) A large fleet of four-stretcher ambulances is essential for life saving. Fourteen thousand ambulances were made in England and Scotland by purchasing used cars, stripping them and then mounting a simple ambulance body on the chassis. London uses over 1500 such ambulances and 550 sitting-case cars. The use of tradesmen's trucks proved universally unsatisfactory; three out of four never arrived on the scene, and lives were lost owing to the delay and confusion. Because of the large number of casualties to be transported in a few hours, no ambulances that carry less than four stretchers are employed. For the simultaneous evacuation of damaged hospitals, a fleet of 200 converted buses carrying 10 stretcher cases and 6 to 10 sitting cases are immediately available, and another 200 are obtainable within two hours.

(4) Casualty stations (British fixed first-aid posts) are necessary at or near all hospitals and at places more than a mile from hospitals to care for minor casualties that do not require hospitalization. Many are now on a care-and-maintenance basis and are activated only during a raid. When functioning, the staff usually consists of one or two doctors, several nurses and a variable number of aides and auxiliaries.

(5) In large cities, casualty stations need not be more numerous than one per 25,000 inhabitants; they should be located about a mile apart. There are less than 300 in the London area, with a population of about 10,000,000 and a land area more than twice that of Greater New York. In smaller, thinly settled communities, they are more numerous in relation to population, but the distances between them are proportionately greater than in metropolitan cities. Many of the minor casualties are moved to first-aid posts in sitting-case cars; some walk.

(6) First-aid parties (stretcher teams) are not necessary, are a waste of manpower and are rapidly being eliminated. First aid at incidents is essentially a function of the rescue parties (rescue teams), which extricate the casualties from under the debris of demolished buildings. All first-aid parties in England and Scotland are therefore being merged into the rescue parties. They include a leader, an assistant leader and eight other members, and are entirely independent of the fire department. They are a life-saving service related to the medical services concerned in field casualty work.

(7) The experiences of Britain under air-raid conditions have dispelled many preconceived notions concerning first aid. Almost all raids occur at night; the victims are crushed under the debris of demolished buildings and are either dead or severely injured; less than a third are slightly injured and can be cared for at casualty stations; all the severely injured must go to a hospital; victims are invariably covered with dust and dirt, which hangs in the air for hours. The conditions under which the rescue workers encounter the injured beneath the structural debris, the darkness, and the dust that always fills the air, the large proportion of dead and severely injured, and the urgent need for immediate

hospitalization make it impossible to apply most peace-time concepts of first aid.

(8) Wounds are usually grossly contaminated and need only be covered with a shell dressing until the casualty reaches the hospital. Hemorrhage is usually controllable with a pressure dressing. The tourniquet is rarely employed. Burns are covered only with sterile gauze until the casualty arrives at the hospital. Tannic acid jelly as a first-aid dressing for burns has been discarded because of the dirt that invariably contaminates the burned surface, because the jelly deteriorates rapidly and, lastly, because tannic acid ignites in the presence of phosphorus when applied to burns caused by the explosion of phosphorus-oil bombs.

(9) Traction splints are not used. An exception is made if the casualty must be transported a long distance over country roads. Unlike Army field experience in the last war, the few miles of travel to a hospital over the paved roads of a city do not warrant the application of traction, especially as the darkness and the conditions of an air raid also make hurried application of the procedure difficult or impossible. All that can be done is to place the fractured extremity gently in alignment, bind it with triangular bandages to the uninjured leg or to an improvised splint, or apply a Thomas splint if one is on hand. Movement of the fragments can also be minimized by snug application of the blankets according to the Wanstead technic of blanketing and by the use of sandbags, which should always be carried in the ambulance.

(10) Shock is treated at the incident by prompt administration of adequate doses of morphine (up to $\frac{1}{2}$ gr. for adults), coramine, proper blanketing, administration of fluids, and the use of hot-water bottles during transportation to the hospital. The use of plasma or blood transfusion is deferred until arrival at the hospital; it is ordinarily quite impossible in the darkness, dirt and confusion at the incident.

(11) The presence of a physician at the incident is invaluable, but more than one is unnecessary. In fact, one physician may cover several nearby incidents, leaving his nurse or one of the nursing auxiliaries of his emergency team at the incident while he moves temporarily from one to another in the immediate neighborhood.

(12) Even though a single night's casualties requiring hospitalization may total 1000 or 2000, large hospitals rarely receive more than 50 to 100, the load being distributed as evenly as possible throughout the city.

(13) A large casualty receiving hospital is often related to one or more peripheral hospitals in the suburbs or in a country district. There are now four base-hospital beds for each casualty bed in the cities.

(14) On receipt at a local report and control center of a message from an air-raid warden that an incident and casualties have occurred, an "express party" is immediately dispatched to the scene. An "express party" includes one rescue first-aid party, one ambulance, one sitting-case car, and one mobile medical unit (mobile medical team). The latter consists of one physician, one nurse and two auxiliaries. No other equipment and personnel of the emergency medical service is dispatched unless additional assistance is requested by the incident officer (usually a higher police official) or by the incident physician on the scene. In this manner, useless movement is avoided and equipment and personnel of the community is carefully conserved.

NUMBER 27

BRONCHIAL OBSTRUCTION AND TRACHEOBRONCHIAL TUBERCULOSIS*

EDWARD B. BENEDICT, M.D.†

BOSTON

SINCE the careful studies of Clerf,¹ Eloesser,² and Samson,^{3,4} bronchoscopy in tuberculosis has been found to be increasingly important. In the early days it was thought that this procedure would be hazardous to the tuberculous patient and might result in spreading the infection, but this has not proved to be the case. On the contrary, knowledge concerning the presence or absence of disease in the tracheobronchial tree obtained by the use of the bronchoscope has been of great aid to the internist and thoracic surgeon in planning treatment.

Tracheobronchial tuberculosis may take three principal forms: the ulcerative, in which there is a diffuse or circumscribed loss of mucosa; the hyperplastic, where there is submucosal proliferation and sometimes the formation of conglomerate tubercles; and the stenotic, in which there is definite scar-tissue formation leading to partial or complete bronchial obstruction.

The indications for bronchoscopy in tuberculosis are as follows: obstructive signs and symptoms as shown by atelectasis, wheeze, difficulty in raising sputum, persistent cough or dyspnea and intermittent febrile attacks; positive sputum when parenchymal disease is controlled or absent; hemorrhage, unexplained by parenchymal disease; and contemplated collapse therapy to determine the possible presence of tuberculosis in the trachea or contralateral bronchus.

In a previous paper⁵ I called attention to 4 cases having symptoms of intermittent bronchial obstruction following thoracoplasty, all of which were relieved by bronchoscopic aspiration of secretions with bougienage. One patient in this group later required lobectomy.

Tuberculous stricture of the bronchus following thoracoplasty may produce an almost complete

obstruction, which can often be markedly relieved by repeated bronchoscopic dilatation.

Since there are many other causes of bronchial obstruction, let us first consider the differential diagnosis. The clinical history, together with the X-ray and laboratory findings, may often lead to a correct presumptive opinion concerning the cause of bronchial obstruction, but in the last analysis only direct bronchoscopic study with biopsy of the lesion will give the final histologic diagnosis. As examples the following cases are cited.

CASE 1. G. E. H. (M. G. H. U216741), a 27-year-old man, first entered the hospital because of cough and

FIGURE 1. Case 1.

Atelectasis of right lung; presumptive diagnosis, adenoma; bronchoscopic biopsy, epidermoid carcinoma, Grade III.

hemoptysis of 10 months' duration. X-ray examination (Fig. 1) showed complete atelectasis of the right lung.

*From the Massachusetts General Hospital. Presented at the annual meeting of the Section of Radiology and Physiotherapy, Massachusetts Medical Society, Boston, May 27, 1942.

†Instructor in surgery, Harvard Medical School, associate visiting surgeon, Massachusetts General Hospital, consulting surgeon, Massachusetts Eye and Ear Infirmary.

Because of the patient's youth the presumptive diagnosis was benign adenoma of the right main bronchus. Bronchoscopy,* however, revealed a malignant tumor, which was biopsied and reported as epidermoid carcinoma, Grade III.

CASE 2. W. M. R. (M. G. H. U224885), a 56-year-old man, entered the hospital complaining of cough and hemoptysis of 1½ years' duration. X-ray examination

to a report of metastatic sarcoma. Following partial bronchoscopic removal there was temporary improvement, with some re-expansion of the left upper lobe.

Another cause of partial bronchial obstruction is sarcoid. In a case previously reported,⁶ the chief complaints were dyspnea and wheeze. The chest x-ray finding was that of sarcoid. Bron-

FIGURE 2. Case 2.

A—Collapse of left lower lobe, with a mass at left hilus; presumptive diagnosis, carcinoma; bronchoscopic biopsy, benign adenoma. B—Following removal of adenoma, persisting collapse of left lower lobe, without hilar shadow; patient asymptomatic.

(Fig. 2A) showed a mass in the left hilus with collapse of the left lower lobe. Because of the patient's age the presumptive diagnosis was bronchogenic carcinoma. Bronchoscopy, however, showed a smooth, round, lobulated tumor arising in the left-lower-lobe bronchus. A biopsy specimen was reported as benign adenoma. Following bronchoscopic removal the patient has remained essentially symptom free for the past 2½ years. The collapse of the left lower lobe persists but the mass in the left hilus has disappeared (Fig. 2B). The bronchoscopic appearance of the adenoma is shown in Figure 3.

A rare cause of bronchial obstruction is metastatic tumor.

CASE 3. W. C. P. (M. G. H. U30702), a 42-year-old man, first entered the hospital in 1938, at which time a sarcoma of the testicle was removed. Nine months later he was readmitted because of bronchial obstruction with collapse of the left lung. X-ray examination (Fig. 4) showed masses in the right-lung field consistent with metastatic tumor and a complete collapse of the left lung. Bronchoscopy demonstrated a ragged tumor mass obstructing the left main bronchus, a biopsy of which led

choscopy showed sarcoid involving the carina and both main bronchi, confirmed by biopsy. There was definite improvement following bronchoscopic removal of the tissue and secretions.

The following cases illustrate different manifestations of tracheobronchial tuberculosis.

CASE 4. A. R. (M. G. H. U84531), a 29-year-old woman, gave a 7 years' history of tuberculosis, with cough and positive sputum. She had had a left phrenicectomy. During the previous year there had been intermittent periods of fever, with increased cough and sputum. X-ray examination (Fig. 5) showed complete collapse of the left lung with cavitation. At bronchoscopy, almost complete obstruction of the left main bronchus 2 cm. below the carina was demonstrated. The stricture was smooth and no ulceration was seen. It was dilated by the passage of esophageal bougies (sizes 8 to 12). No follow-up was obtainable, as the patient lived at a distance.

This patient had a positive sputum, and bronchoscopy confirmed the presumptive diagnosis of tuberculous stricture.

*All bronchoscopies were performed by me except those in Cases 9 and 10, performed by Dr. Lowrey F. Davenport, and the first bronchoscopy in Case 14, performed by Dr. Ralph H. Adams.

CASE 5 C M D (M G H U346536), a 26-year-old woman, gave a long-standing history of pulmonary tu-

FIGURE 3 Case 2

Bronchoscopic appearance of multilobular tumor adenoma

berculosis and tuberculous laryngitis with positive sputum. She had been treated by partial right pneumothorax and left oleothorax. X-ray examination (Fig 6) showed the

FIGURE 4 Case 3

Atelectasis of left lung due to sarcoma of bronchus metastatic disease also in right lung field

right lung half collapsed and herniated across the midline. There was oil on the left side and possible partial occlusion of the left main bronchus. At bronchoscopy the

left main bronchus 2 cm below the carina was narrowed to a 3 mm lumen. The stricture was smooth and fibrous. It was dilated by the passage of esophageal bougies (sizes 12 to 16). There were no retained secretions. A smear taken from the stricture showed tubercle bacilli.

CASE 6 A W P (M G H U329952), a 38-year-old man, entered the hospital because of chronic cough and positive sputum. X-ray examination (Fig 7) showed partial collapse of the right upper lobe, with probable cavitation and stenosis of the right upper lobe bronchus. Bronchoscopy demonstrated reddening and almost complete stenosis of the right upper lobe bronchus, with two pinpoint tubercles (Fig 8). The stenosis was best seen by the use of the right-angle telescope⁸ (Fig 9). Since the disease was confined to the right upper lobe and tr-

FIGURE 5 Case 4

Atelectasis of left lung positive sputum tuberculous stricture of left main bronchus

reparable damage to this lobe had already occurred, lobectomy was performed by Dr. E. D. Churchill, with success. The pathologic specimen showed no cavitation but moderate bronchiectasis, with very extensive microscopic bronchial tuberculosis throughout the lobe. The patient made a satisfactory recovery and has been essentially symptom free for 7 months since the operation.

In the above 3 cases positive sputum for tuberculosis made the diagnosis fairly obvious. In some of the following cases, however, the sputum was negative and the diagnosis was more obscure.

CASE 7 V D (M G H U253261), a 28-year-old woman, entered the hospital complaining of cough, fever and chills of 1 year's duration. The sputum had been negative for tubercle bacilli on ten examinations. X-ray examination (Fig 10) showed calcified lymph nodes and collapse of the right lower lobe. The X-ray Department made a tentative diagnosis of tuberculosis in spite of the negative sputum. Bronchoscopy revealed distortion of

the right bronchial tree with outcropping near the bifurcation of the lower lobe. The biopsy diagnosis was tuberculosis. Pneumonectomy was later performed by Dr. Richard H. Overholt.

CASE 8. M. L. K. (M. G. H. U271988), a 59-year-old man, entered the hospital because of recurrent attacks of hemoptysis. The sputum on several occasions had been negative for tuberculosis. X-ray examination (Fig. 11) showed probable tuberculosis of the left upper lobe, with bronchiectasis. Bronchoscopy, however, revealed a 7-mm ulcer of the right stem bronchus, the ulcer having sharp margins and a dirty base. A smear taken from the ulcer was positive for tuberculosis. A year and a half later

FIGURE 6. Case 5.

Partial collapse of right lung, with pneumothorax, herniation of right lung across the midline, left pleurothorax, positive sputum, tuberculous structure of left main bronchus.

the patient's physician reported that he was getting along satisfactorily under medical care.

It is noteworthy in this case that most of the disease was assumed to be in the left upper lobe, but bronchoscopy showed an active, ulcerating lesion in the right stem bronchus. Information of this sort is naturally of very great importance, especially if any surgical treatment is contemplated. Moreover, bronchoscopy in this case, as in Case 7, was the only method of examination to yield a positive diagnosis.

CASE 9. T. F. (M. G. H. U205925), a 28-year-old woman, entered the hospital with a 3-year history of cough, fever and wheeze. Left pneumothorax had been necessary every 6 weeks. Tubercle bacilli had never been found in the sputum on repeated examinations. X-ray examination (Fig. 12) showed complete collapse of the left lung, with cavity formation. Bronchoscopy demonstrated that the left main bronchus was completely oc-

cluded by a red, elevated, fungating mass, from which a biopsy was obtained, the pathological report being tuber-

FIGURE 7. Case 6.

Partial collapse of right upper lobe, with cavitation, positive sputum.

culosis. Eight months later a second bronchoscopy showed the left main bronchus almost completely stenosed and represented by only a small dimple in the mucous mem-

FIGURE 8. Case 6.

brane of the trachea. There was no evidence of tuberculosis in the trachea or right main bronchus. Accordingly, Dr. Churchill performed a left pneumonectomy. Unfortunately, however, in spite of all precautions taken, the

disease progressed in the right lung and the patient died 1½ years later

Cases 7, 8 and 9 illustrate the importance of bronchoscopy in establishing a positive diagnosis of

FIGURE 9

tuberculosis when all sputum examinations have been repeatedly negative

CASE 10 J J McC (M G H 46518), a 45-year-old man, entered the hospital with a 20-year history of cough

FIGURE 10 Case 7

Atelectasis of right lower lobe with calcified lymph nodes, negative sputum, bronchoscopic biopsy tuberculosis of right lower lobe bronchus

and a 6-month history of hemoptysis. Sputum was expectorated up to a cupful each day and had several times been positive for tuberculosis. X-ray examination (Fig 13) showed a mass at the right hilus, with cavitation. Because of the positive sputum tuberculosis was

considered likely although carcinoma was also mentioned. Bronchoscopy revealed an irregular fungating mass near

FIGURE 11 Case 5

Probable tuberculosis of left upper lobe, negative sputum, bronchoscopic examination of right stem bronchus, bronchoscopic smear from ulceration

of the right middle lobe since the final diagnosis was epidermoid carcinoma Grade IV. Pneumonectomy was

FIGURE 12 Case 9

Atelectasis of left lung, sputum negative, bronchoscopic examination, fungating mass in left main bronchus, bronchoscopic biopsy tuberculosis

therefore performed by Dr Churchill. Five years later the patient was fairly comfortable although complaining of some dyspnea and cough.

In this case clinical evidence pointed chiefly to tuberculosis, but bronchoscopy disclosed a bronchogenic carcinoma in addition to the tuberculosis.

CASE 11. M. E. W. (M. G. H. U189707), a 57-year-old woman, entered the hospital complaining of wheeze of 2

FIGURE 13. Case 10.

Right hilar mass, with cavitation; positive sputum; bronchoscopic biopsy, epidermoid carcinoma, Grade IV.

months' duration. There was almost no cough or sputum. Sputum examinations on several occasions were negative

FIGURE 14. Case 11.

Atelectasis of left upper lobe; partial atelectasis of left lower lobe; sputum negative; bronchoscopic examination, multiple tubercles in left main bronchus; bronchoscopic aspirations, positive in guinea pig.

for tuberculosis. X-ray examination (Fig. 14) showed complete collapse of the left upper lobe and partial col-

lapse of the left lower lobe. The findings were interpreted as being possibly due to carcinoma, although the pointed extremity of the left main bronchus and numer-

FIGURE 15. Case 11.

ous calcified glands raised the possibility of a benign tuberculous stricture. Bronchoscopy (Fig. 15) showed multiple tubercles extending down the left main bronchus all the way from the carina to the partial stenosis. A

FIGURE 16. Case 12.

Atelectasis of right lower and right middle lobes (portable film); clinical diagnosis, bronchogenic carcinoma with brain metastases; bronchoscopic biopsy, acute and chronic inflammation (? tuberculosis); subsequent sputum positive.

guinea pig inoculated with bronchoscopic aspiration developed tuberculosis. X-ray treatment was given, with definite improvement. Three years later the patient re-

ported no further upsets, no cough, negative sputum and some wheeze. X-ray examination showed fibrosis of the left upper lobe.

In this case bronchoscopic examination resulted in a positive diagnosis of tuberculosis, for which X-ray treatment was subsequently given.

CASE 12. B. F. (M. G. H. U235515), a 62-year-old woman, entered the hospital complaining of 2 years' wheezing, 4 days' fever and 1 day's drowsiness and headache. Thirty years previously she had had pleurisy with effusion. Otherwise there was nothing to suggest tuber-

culosis. In this case bronchoscopic examination resulted in a positive diagnosis of tuberculosis, for which X-ray treatment was subsequently given.

FIGURE 17. Case 13.

Upper right thoracoplasty, followed by persistent cough, positive sputum and wheeze; bronchoscopic examination, multiple tubercles in right main and right stem bronchi; later, complete stenosis.

culosis. X-ray examination (Fig. 16) showed collapse of the right lower and right middle lobes (portable film). A chest consultant decided that the probable diagnosis was bronchogenic carcinoma with brain metastases. Bronchoscopy, however, disclosed a nodular lesion of the right stem bronchus with central necrosis. The gross appearance was consistent with carcinoma. The biopsy diagnosis was acute and chronic inflammation, with necrosis and possible tuberculosis. The sputum subsequently was positive for tuberculosis. Two years later the patient was making a slow but constant improvement on medical management.

This case is the reverse of Case 11, as here the probable clinical diagnosis was carcinoma, but bronchoscopy showed tuberculosis.

CASE 13. J. G. (M. G. H. U153402), a 46-year-old woman, gave a history of right phrenicectomy for tuberculosis 2 years before entry. One year previously she had undergone a two-stage thoracoplasty, followed by persistent cough, positive sputum and wheeze. X-ray exami-

nation (Fig. 17) showed an upper right seven-rib thoracoplasty. Because of persistent cough, positive

FIGURE 18. Case 14.

FIGURE 19. Case 14.

Low-power cross section of bronchus, showing markedly reduced lumen.

months later bronchoscopy was repeated and the process was found to be more advanced, with stenosis of the right stem bronchus and involvement of the left main bronchus. Two years later on a medical regimen there was still moderate cough but less wheeze, and some slow improvement.

Bronchoscopy in this case demonstrated the presence of active tracheobronchial tuberculosis following thoracoplasty.

CASE 14. H. V. (M. G. H. U295413), a 42-year-old woman, entered the hospital complaining of left-sided

tive diagnosis was carcinoma of the esophagus, with involvement of the recurrent laryngeal nerve and invasion of the tracheobronchial tree. Esophagoscopy, however, showed a normal esophageal mucosa with evidence of extrinsic pressure. Bronchoscopy revealed an extensive proliferative mass involving the left main bronchus, the

FIGURE 20. Case 15.

A—Upper mediastinal mass in patient with cough, hoarseness and dysphagia. B—Apparent destruction of esophageal mucosa; presumptive diagnosis, carcinoma of esophagus; esophagoscopy, negative; bronchoscopic biopsy, bronchial tuberculosis.

wheeze and positive sputum associated with pulmonary tuberculosis of the left lung. Bronchoscopy prior to entry had shown an ulcer of the left main bronchus. Bronchoscopy showed narrowing of the left main bronchus in the region of the left-upper-lobe orifice. There was no evidence of activity. The appearance was that of a healed bronchial ulcer. A first-stage thoracoplasty was undertaken, followed by persistent wheeze. A second bronchoscopy, 6 months later, revealed a stricture of the left main bronchus just above the left upper lobe. The positive sputum persisted. X-ray examination (Fig. 18) showed fibrosis and calcification. A third bronchoscopy, 5 months later, again demonstrated stricture of the left main bronchus 2 cm. below the carina. There was no ulceration, and the lumen was only 3 cm. in diameter. Pneumonectomy was therefore performed by Dr. Churchill. The postoperative course was satisfactory and 3 months later the patient was reported as doing well. The reduced lumen of the left main bronchus is shown in a low-power cross section in Figure 19.

CASE 15. A. J. P. (M. G. H. U328726), a 38-year-old man, entered the hospital complaining of cough of 13 months' duration, hoarseness for 11 months and dysphagia for 5 weeks. Mirror laryngoscopy showed the left vocal cord to be paralyzed in the midline. X-ray examination (Fig. 20A) revealed a mass in the upper mediastinum, with narrowing of the esophagus and apparent destruction of the esophageal mucosa (Fig. 20B). The presump-

carina and the right main bronchus. The tissue removed at the time of bronchoscopy was reported as showing evidence of tuberculosis.

This is obviously a very unusual case, for several reasons. Paralysis of a vocal cord is common in malignancy but rare in tuberculosis. The dysphagia appeared to be the presenting symptom but was apparently overemphasized, for the cough and hoarseness preceded it. However, most of the clinicians concluded that there was a probable malignancy of the esophagus. Bronchoscopy and esophagoscopy demonstrated the true nature of the process.

CONCLUSIONS

Among the most frequent causes of bronchial obstruction are carcinoma, benign tumor and tuberculosis.

The clinical picture may lead to an erroneous presumptive diagnosis, for the underlying cause of the obstruction frequently cannot be determined by laboratory and x-ray studies.

Bronchoscopy with biopsy or smear is necessary to establish a positive diagnosis.

THE USE OF SULFADIAZINE IN THE MANAGEMENT OF SIMPLE MASTOIDECTOMY WOUNDS

LIEUT CHARLES A TUCKER, MC, AUS,* AND MAJOR CARLYLE G FLAKE, MC, AUS†

BOSTON

IN SEPTEMBER, 1941, Livingston,¹ of Chicago, reported a series of 13 cases in which sulfonamide drugs were used locally in mastoid cavities, the wounds being closed without drainage. The results were remarkable in that the postoperative course was greatly shortened. Apparently, this was the first report of the local use of sulfonamide drugs in mastoidectomy wounds, although they had previously been used in the treatment of compound fractures and peritonitis, as is well known.

The primary closure of mastoidectomy wounds without drainage was not new. Near the turn of the century it was a common practice among reputable otologists to close the wound after it had been allowed to fill with a blood clot—the so-called "blood clot method." Sprague² and Reak³ among others, reported considerable success. They described how the blood clot became organized and filled in by the growth of fibroblasts and osteoblasts. This method fell into disuse, however, because it was quite unsuccessful in the hands of many surgeons; the clot frequently broke down, and the wound opened and subsequently healed by the slow process of granulation. Nevertheless, otologists were influenced to the extent that, instead of packing the mastoid wounds wide open, a method was devised whereby a drain was inserted in the cavity and the wound closed except at the site of the drain. This procedure has been generally employed up to the present day.

From the results of Livingston's report, however, one might assume that local chemotherapy would exert a sufficient bacteriostatic or bactericidal effect to make a primary closure feasible in a high percentage of cases. Yet there remained a reasonable doubt concerning the validity of his results, since these cases, as reported, were not controlled.

With this latter point in mind, we studied a series of controlled cases in which operation was per-

formed at the Children's Hospital from October, 1941, through June, 1942. The present report is a summary of observations from these cases.

All cases were those in which the present illness was six weeks or under in duration and in which no sulfonamides had been given before hospital admission. The period of six weeks was a purely arbitrary one which, for the purpose of simplicity, we called the stage of acute mastoiditis. The series was then divided into three parts. Group A comprised those cases in which sulfadiazine⁴ was placed directly in the mastoid wound at the close of operation and the wound was sutured without drainage. No sulfonamides were given by mouth. The Group B cases received sulfadiazine by mouth, both preoperatively and postoperatively, and the wound was sutured without drainage, no sulfadiazine being given locally. The Group C cases received no sulfonamide, either by mouth or within the wound, which wound was drained at the lower pole by a small wick of gutta serena gauze.⁵

These cases were taken in rotation, Case 1 being placed in Group A, Case 2 in Group B, Case 3 in Group C, Case 4 in Group A, and so on. With the series controlled in this fashion, we hoped to rule out certain errors. First, the year to year variation in the severity of acute mastoiditis and its sequelae would be obviated. Secondly, there was a strong possibility that the level of sulfadiazine in the blood stream might be a factor in rapid healing. Sulfadiazine levels, in those who received sulfadiazine by wound only, showed values as high as 15 mg per 100 cc of whole blood, although in most cases the level was 1 mg per 100 cc or less. The level five days postoperatively was usually less than 1 mg per 100 cc.

⁴The sulfadiazine used in this series was kindly supplied by the Lederle Laboratories, Pearl River, New York.

⁵Another group is readily apparent for its control value, that in which the wound is closed without drainage and without sulfonamides. This procedure was not undertaken since we did not believe that it would prove to be of sufficient value to subject the patient to the necessary risk.

TECHNIC

Group A

A complete simple mastoidectomy was performed in each case in Group A. Care was taken to enlarge the aditus ad antrum, so that in most cases the short process of the incus was exposed. In some cases this was obscured by granulation tissue. After the mastoid bone had been exenterated, the cavity was flushed with warm physiologic saline solution. A piece of gauze dampened with a 1:1000 solution of epinephrine was then placed in the cavity and interrupted periosteal sutures were taken with No. 0 or 00 plain catgut, but not tied. The pack was then removed and sulfadiazine powder was poured into the cavity from a sterile test tube. The periosteal sutures were tied. No attempt was made to pack the light, fluffy powder into the cavity. Some of the powder was dusted freely into the subcutaneous regions and along the skin edges. The skin was then closed with interrupted black-silk sutures, using the Poole mattress stitch. No pack was placed within the external auditory canal. From 0.5 to 2.0 gm. of sulfadiazine was used in each case, depending on the size of the cavity. The sulfadiazine had been previously autoclaved in cotton-stoppered test tubes at 270°F. for ten minutes. The adenoids were removed following mastoidectomy whenever they were found to be hypertrophied by palpation, roentgen examination or nasopharyngoscopy. Dressings were usually done on the second postoperative day, at which time it was possible to replace the bulky dressing applied at operation with a small postaural piece of gauze. Sutures were removed on the sixth to the eighth postoperative day. The ear canal was kept free of discharge by wiping with dry cotton swabs every four hours as long as needed.

Group B

A similar operation with closure was performed in Group B, the chief difference being that the sulfadiazine was not used locally, but instead was given by mouth for one day preoperatively and for seven to ten days postoperatively, in amounts sufficient to produce a blood level of 10 to 15 mg. per 100 cc. Postoperative dressings were essentially the same.

Group C

The operation in Group C was similar to that in Groups A and B. The wound was closed as in the first two groups, except at the inferior pole, where a gutta-percha gauze wick was inserted, extending up to the antrum. This wick was replaced on the second postoperative day by a small piece of rubber tissue, which was removed and re-

inserted every other day until drainage was minimal, at which time the wound edges at the lower pole were allowed to seal over.

ANALYSIS OF RESULTS

Group A

The number of patients in Group A, in which sulfadiazine was used locally and the wound was sutured, was 16 and the number of cases of mastoiditis operated on 22, there being 6 cases of bilateral mastoidectomy. Of these 6, 2 cases deserve special mention. In one, the wound was closed on the right with sulfadiazine and drained on the left without sulfadiazine. The results here were entirely opposite from the remainder of the series, in that the drained ear ceased to discharge on the ninth postoperative day and the wound was healed on the seventeenth postoperative day, whereas the undrained ear discharged for thirty-three days. In another case, treated similarly, the undrained side healed in eight days, the drained side in twenty-four days.

In all, twenty operations were performed in which sulfadiazine was placed within the wound. All the wounds healed per primam. There were no complications, with the exception of one case that developed a subcutaneous postaural abscess on the eighteenth postoperative day, necessitating incision and drainage, with healing complete four days later. These cases, along with the other two groups, are summarized in Table 1.

Bacteriologic findings. Sixteen wounds showed beta-hemolytic streptococcus in pure culture, 1 showed beta-hemolytic streptococcus and *Staphylococcus aureus*, and 1 *Haemophilus influenzae*. The cultures from 2 wounds showed no growth.

Pathologic changes. All removed tissue revealed pus, granulations or necrosis, alone or in combination. One case had a large subperiosteal abscess, which extended up to the temporal region, causing trismus.

Age. The children varied from nine months to six years and eleven months in age.

Follow-up. This was carried out on every patient and varied from three weeks to six months. One patient developed a postaural abscess after six months, which healed without event. This was the only recurrence of mastoid-cavity infection.

Hospitalization and drainage. The average length of aural drainage was 10.0 days. The average length of time required for both the wound and middle ear to heal, including complications, was 10.1 days.

Group B

The number of patients in Group B, in which sulfadiazine was given by mouth and the wound

was closed, was 15, and the number of operations for mastoiditis 18. Of these, 1 patient had a bilateral mastoidectomy in which the right wound was sutured and the left was drained. Both ears

Follow-up. This varied from one week to four months. There was no recurrence of ear infection.

Hospitalization and drainage. The average length of aural drainage was 8.2 days. The average

TABLE 1 Data on the Three Groups of Patients

DETAILS	GROUP A	GROUP B	GROUP C
Number of patients	16	15	15
Number of ears operated on	20	17	16
Age incidence	9 mo to 6 yr 11 mo	10 mo to 8 yr 8 mo	5 mo to 6 yr 4 mo
Wound healing	Per primam	Per primam except for 2 cases	Healing complete in 3 wk (11 cases)
Average days of aural discharge	10.0	8.2	Over 15 days
Bacteriology (operative wound culture)	16 beta hemolytic streptococcus 1 beta hemolytic streptococcus and <i>Staph aureus</i> 1, <i>H influenzae</i> 2, no growth	3 beta hemolytic streptococcus 1 pneumococcus, 1 gram positive rods 10 no growth	10 beta hemolytic streptococcus 1 beta hemolytic streptococcus and <i>Staph aureus</i> , 1 pneumococcus, 4 no growth
Complications	1, subcutaneous postaural abscess on 18th postoperative day	1 wound broke down 1, wound became infected 1 wound developed stich abscess	1 subcutaneous wound infection with healing by secondary intention 1 cavity revised after 4 wk 1 cavity revised after 7 wk
Average days of hospitalization	10.1	9.0	Over 21

ceased to discharge in six days. The right wound healed per primam. The left healed entirely except at the drain site, where final healing occurred on the fifteenth postoperative day.

In all, 17 mastoid processes were operated on by this method. Of these, 15 healed per primam. One developed a subcutaneous wound infection on the fifth day, which healed by the tenth day. In another case, a bilateral mastoidectomy, the left postaural wound broke down and had to be re-sutured. Final healing took place on the twentieth postoperative day. Two cases had small stich abscesses.

Bacteriologic findings. Cultures from the mastoid processes showed beta-hemolytic streptococcus in 5 wounds, pneumococcus (not typed) in 1, gram-positive rods (not identified in 1), and no growth in 10. This is a large number of negative cultures, explained perhaps by the fact that sulfadiazine was given by mouth preoperatively. The ears on admission showed a much greater number of positive cultures for pathogenic organisms, only 3 being nonpathogenic.

Pathologic changes. All removed tissue revealed pus, granulations or necrosis, alone or in combination. In one case there was a definite perisinus abscess, and in another granulations were present on the sinus. One case developed a subperiosteal abscess.

Age. The children varied from ten months to eight years and eight months in age.

of the time for both the wound and middle ear to heal, including complications, was 9.0 days

Group C

The number of patients in Group C, in which no sulfadiazine was given and the wound was drained, was 15, and the number of mastoid processes operated on 16. Of these patients, 10 had an uneventful convalescence. In 1 case, the wound edges separated and healed by secondary intention. In 4 cases, the mastoid cavities were revised after five to seven weeks of drainage.

Bacteriologic findings. Of the cultures from mastoid wounds, 10 showed beta-hemolytic streptococcus, 1 showed beta-hemolytic streptococcus and *Staph. aureus*, 1 pneumococcus (not typed), and 4 no growth.

Pathologic changes. All removed tissue revealed pus, necrosis or granulations, alone or in combination. Two cases showed subperiosteal abscesses.

Age. These children varied from five months to five years and four months in age.

Follow-up. This ranged from one week to six months. Two cases showed recurrent aural discharge, 1 as a result of measles. Both cases healed uneventfully. One case was reoperated on after five weeks and 3 after seven weeks of continued wound or ear drainage. Ordinarily, these might have been allowed to drain considerably longer. It is interesting to note that 3 patients were infants under one year of age with poor nutrition.

Sulfadiazine was used at the second operation, with prompt healing, in 3 of the 4 reoperated cases.

Hospitalization and drainage. The length of time of aural discharge averaged 15 days, and wound healing averaged 3 weeks, except for the 4 cases that were revised. In these, the convalescence was considerably prolonged.

DISCUSSION

On final analysis, the results obtained in this series of mastoidectomies seem to be significant. Although the number of cases in each group is quite small, the startling differences in the postoperative courses at least warrant further study. Study of postoperative audiograms would be of considerable interest in the final evaluation of our results, but this was not particularly feasible since all the patients were children. However, it was our impression that the hearing was not altered appreciably in those with sulfonamide therapy, since these children have had, after six weeks at the most, normal tympanic membranes and no marked loss of hearing by cursory examination.

The choice of any one of the sulfonamides in preference to others is still an open question. Sulfanilamide has been advocated for use locally because of its high solubility. However, the solubility seems to be relatively unimportant, provided that the opening into the middle ear is enlarged. In this way, the cavity decompresses itself. In most of our cases, we recovered sulfadiazine crystals suspended in the serous aural discharge. Perhaps the lesser soluble substance has a more prolonged local action. It is the opinion of one of us (C. A. T.) that a combination of sulfanilamide and sulfadiazine placed within the wound, with small amounts of sulfadiazine given by mouth postoperatively, may be the method of choice. The specificity of the sulfonamide drug used locally probably does not enter into the picture, since, at the concentrations developed locally, all these drugs have a broad bacteriostatic coverage.

Postoperative ear cultures obtained in some of the cases in Groups A and B often showed the offending organism to be present until the ear ceased to discharge. In 2 cases, it was necessary to permit the escape of serum, which had collected beneath the wound. These cases showed a mini-

mal amount of aural discharge, indicating a block, probably in the region of the aditus.

The method of wound closure is still an open question. Guerry and Putney⁴ have reported a series of controlled cases in which a sulfathiazole gauze pack was used. Their results, too, showed a remarkable improvement in postoperative convalescence.

In our series, those who received the sulfonamide by mouth did about as well as those who received it locally. The major difference, however, was in wound healing, which was definitely improved when sulfadiazine was used locally.

SUMMARY AND CONCLUSIONS

A controlled series of 41 cases of simple mastoidectomy is presented, divided into three sets as follows: Group A, those receiving sulfadiazine locally, the wound being closed without drainage; Group B, those receiving sulfadiazine by mouth, the wound being closed without drainage; and Group C, those not receiving sulfadiazine, the wound being drained in the usual fashion.

The hospitalization required in Groups A and B averaged around ten days, the wounds healing per primam and the tympanic membrane being healed and dry at that time. The wound broke down, in only 1 case, in Group B. There were no untoward results. The patients in Group C had the usual prolonged convalescence.

At this time, we cannot advocate with impunity any one method for the control of wounds in mastoidectomy, although sulfonamide therapy seems to be of definite value. Certainly the prime requisite for good results is the performance of a standardized, thorough, simple mastoidectomy.

This report, based on relatively few cases, is presented for the objective data that it contains. When it is taken together with other similar reports, which will undoubtedly appear in the literature, the correct procedure for the control of mastoidectomy wounds will eventually arise.

CHRONIC MILIARY TUBERCULOSIS

Report of a Case

EDWARD JAMES WELCH, M.D.*

BOSTON

IN 1937, Hoyle and Vaizey¹ published their monograph on chronic milary tuberculosis, presenting 120 cases collected from the literature and from their own experience. Since the publication of their book, several additional cases have been reported. These reports have served to demonstrate the benign course that may be followed by a disease that only recently was considered to be invariably fatal.

AGE INCIDENCE

Chronic milary tuberculosis has been recorded at almost all ages, from the first to the seventieth year of life. The majority of cases occur in the second, third or fourth decade. Distribution between the sexes is approximately equal. An insignificant number of patients give a history of tuberculosis. Other previous illnesses and family histories of tuberculosis have a questionable influence on the incidence.

SYMPTOMS AND SIGNS

In most cases the onset is insidious, with slight symptoms and signs. Cough, expectoration and dyspnea are the commonest pulmonary symptoms, and these are usually mild. In some cases a cold dates the onset of the disease. Loss of weight and weakness are frequent constitutional complaints. Symptoms of extrapulmonary tuberculosis first bring some cases under observation.

The physical signs are inconstant. Slightly over half the cases present wasting and fever, the latter usually of mild degree. The commonest abnormal physical signs are those in the lungs, but even these are absent in one fifth of the cases. The pulmonary findings vary from localized evidence of infiltration to signs of generalized pulmonary involvement. Of the extrapulmonary signs, splenic enlargement and lymphadenopathy predominate. A small number of cases present evidence of tuberculosis of the bones or joints.

RADIOLOGIC FINDINGS

The only constant objective finding of chronic milary tuberculosis is the typical appearance of the pulmonary lesions in roentgenograms of the chest. In all except a few cases the distribution is bilateral,

with total pulmonary involvement. In addition to the usual small, soft, ill defined lesions, occasional larger areas of infiltration or excavation are seen. The roentgenographic picture is in most cases indistinguishable from that of acute milary tuberculosis.

Sayé² has described a nonapparent form of chronic milary tuberculosis, which he detected in over 5 per cent of students examined radiologically at the University of Barcelona. These cases exhibited fine linear and nodular shadows in the lung fields. The significance of the lesions was to be determined by subsequent examinations. As yet no confirmatory series of similar cases has been reported elsewhere.

LABORATORY DATA

A bacteriologic diagnosis can be established in about half of all cases, and a histologic diagnosis in an additional small percentage (15 to 20 per cent) during life. Necropsy establishes the diagnosis in another 10 per cent, although even here the tubercle bacillus is often not demonstrated. Altogether, there remain about one fifth of all cases without bacteriologic or histologic evidence to support the diagnosis. In this group, the symptoms, physical signs, typical roentgenographic findings and clinical course warrant the diagnosis.

The tuberculin test has been reported in only a few cases, and in some has been negative. The failure to find the tubercle bacillus and the presence of a negative tuberculin test, even where the histologic findings are consistent with tuberculosis, leave room for doubt concerning the accuracy of the diagnosis. The close resemblance of chronic milary tuberculosis to Boeck's disease has undoubtedly led to the improper classification of many cases.

CLINICAL COURSE

Where to draw the line between acute and chronic milary tuberculosis is difficult to decide. Hoyle and Vaizey¹ considered that chronic cases should present a clinical course of at least three months. They found that of 64 patients sufficiently observed, 13 died within six months, 33 died within eight years (with an average length of life of two years from the date of onset of symptoms), and 18 lived to be considered arrested cases. In

*Assistant in medicine, Boston University School of Medicine, acting chief of staff, Channing House for Tuberculosis, Boston.

those who died, tuberculous meningitis and acute generalized tuberculosis were the leading causes of death. In those who lived to be followed by serial roentgenograms, the lesions appeared stationary in some, became more discrete or calcified in others, and actually disappeared in a few. The reported cases have been too few to offer reliable criteria for predicting the course of the individual patient.

MORBID ANATOMY

In those cases that have come to autopsy, the pulmonary lesions have been most constant. Except in cases terminating with an acute generalized spread of the disease, extrapulmonary lesions have not been frequent. In the lungs, numerous evenly distributed, tiny, gray or white, fibrous miliary foci, sometimes calcified, appear. Rarely are the lesions more than a few millimeters in diameter. Histologically the lesions are characterized by a great amount of fibrous tissue and by scant cellular infiltration in which giant cells and epithelioid cells predominate. Caseation has been unusual.

There has been much argument about the mode of spread of this disease. It is conceivable that a tuberculous lesion erodes the thoracic duct or a blood vessel and discharges tubercle bacilli into the blood stream. Whether a generalized systemic distribution of lesions or a restricted pulmonary distribution occurs depends on whether the channel involved is a part of the greater or lesser circulatory system. This concept of a hematogenous route of dissemination has met with greater popularity than that of a lymphogenous one. That the latter may occur, however, has been well demonstrated by Hoyle and Vaizey in the pathologic findings in one of their cases. The possibility of a bronchiogenic mode of spread must also be recognized, although a uniform dissemination of lesions throughout both lungs by this route would hardly be expected.

DIAGNOSIS

The more usual conditions offering difficulty in the differential diagnosis of chronic miliary tuberculosis are Boeck's disease, generalized carcinomatosis, pneumoconiosis and pulmonary congestion. The exclusion of rare conditions such as fungus infections, periarteritis nodosa and Hodgkin's disease may also present difficulty.

Boeck's disease is often hard to exclude. So closely alike may it and chronic miliary tuberculosis appear, that some clinicians believe both terms to refer to the same disease. A negative tuberculin test, the absence of tubercle bacilli and the presence of characteristic bone lesions in the phalanges are points in favor of the diagnosis of Boeck's disease. Even at necropsy it is often difficult to

differentiate these conditions. Snapper and Pompen³ consider that the absence of tubercle bacilli and of caseation distinguishes Boeck's disease from chronic miliary tuberculosis.

Generalized carcinomatosis may be differentiated by extreme dyspnea, the absence of tubercle bacilli and a rapidly fatal course. There is often an additional history of pain in one or more bones, leading to the discovery of other metastases.

Pneumoconiosis is excluded by the absence of a history of dust exposure.

In pulmonary congestion the preponderance of the opacities and physical signs about the hili and bases of the lungs should serve to indicate this diagnosis. An abnormal size or shape of the heart would also be suggestive.

Proof of the diagnosis of chronic miliary tuberculosis rests, during life, on finding the tubercle bacillus; after death, on finding the characteristic histologic lesions. The bacilli may be found in the sputum or in the extrapulmonary lesions. In a number of cases neither a bacteriologic nor a histologic diagnosis is possible and it becomes necessary to rely on serial roentgenography and the clinical aspects of the case. In the case reported below the diagnosis rested on these two factors alone from 1939 to 1942, when the patient developed a cavity and a positive sputum. The presence of pericarditis with effusion at one time in the course of the disease lent additional weight to the probability of a miliary tuberculous process. No case of chronic miliary tuberculosis with pericardial effusion has, to my knowledge, been recorded before.

TREATMENT

As in all degrees of pulmonary tuberculosis, treatment consists of rest and general hygienic and nutritional care. In a few cases with localized areas of infiltration or excavation, unilateral pneumothorax has been successful in controlling the disease. Partial bilateral pneumothorax has been recommended, but remains untried. Sayé² thought that some of his patients were benefited by injections of Sanocrysin.

CASE REPORT

A. S., a 58-year-old Greek tanner, was admitted to the Middlesex County Sanatorium on July 26, 1939. The past history was irrelevant. There was no history of contact with tuberculosis or exposure to silica-containing dust.

The patient was well until 4 or 5 years before admission, when he first experienced dyspnea on exertion and slight swelling of the ankles in the afternoon. Easy fatigability was sufficient to necessitate stopping work. Intermittent aching in the right side of the chest and a slight cough began at that time, and he began to raise an ounce of thick yellow sputum per day.

The patient tolerated these symptoms, however, and it was not until 15 months before admission that he consulted a physician. At that time his chief complaint

complaint was, as before, a burning pain in the epigastrium. A roentgenogram showed slight clearing of the pleural reaction on the left. He reentered the hospital

FIGURE 1

was a burning postprandial epigastric pain. He was admitted to another hospital, where a diagnosis of chronic gastritis, acute cardiac decompensation and miliary tuberculosis was made. A roentgenogram taken on April 20, 1938 (Fig 1), showed scattered mottled infiltration throughout both lung fields and thickening of the interlobar septum on the right. The lower two thirds of the left lung was obscured by an enormous cardiac shadow extending from the left axilla to a point 5 cm beyond the right pulmonary hilus. The patient was discharged after 3 weeks.

The patient returned to the hospital 7 months later. A roentgenogram on December 9 showed a marked decrease in the size of the cardiac shadow, which was then normal. The right lung showed no change. On the left there was a pleural reaction casting a haze over the entire lung. The tubercle bacillus was not found.

The patient was not heard from again until June 5, 1939, when he came to the Diagnostic Clinic. His chief

complaint was, as before, a burning pain in the epigastrium. A roentgenogram showed slight clearing of the pleural reaction on the left. He reentered the hospital

July 26. There had been no increase of dyspnea, fatigue, swelling of the ankles, cough or expectoration.

Physical examination revealed a well developed, slightly undernourished, tired looking man. The skin was clear. There were a few small, firm, lymph nodes palpable in the neck and in both axillae. Examination of the ears, eyes, nose and throat revealed no abnormality. The optic fundi were clear. The chest was slightly barrel shaped, and expansion was equal on both sides. The lungs were resonant, and the breath sounds vesicular throughout. At the right base posteriorly there was a faint friction rub. A few posttussive medium rales were heard at the left apex posteriorly and in the first left interspace. The heart was of normal size, with a regular rhythm and no murmurs. There was slight sclerosis of the peripheral arteries. The blood pressure was 130/80. The liver and spleen were not felt. The remainder of the examination was negative. Fluoroscopy revealed normal excursion of the diaphragm on each side. The heart was of normal size and contour.

The cardiac outline was indistinct, with a regular beat of fair quality. A roentgenogram of the chest, taken on July 27 (Fig. 2), showed no change.

The red-cell count was 3,900,000, and the hemoglobin

A diagnosis of chronic miliary tuberculosis was made and the patient was discharged, to be followed in the Outpatient Department. At periodic check-ups he complained of abdominal cramps, occasional diarrhea, cough

FIGURE 2.

70 per cent (Sahli). The urine was negative, and there was no blood in the stool.

The patient remained in the hospital for 102 days. The temperature, pulse and respirations remained normal. He raised about 30 cc. of semithick, nonodorous, yellowish sputum daily, which was negative for fungi, and for tubercle bacilli even after inoculation of a guinea pig. He was treated by rest, a bland diet and Sippy powders, with relief of his pain, improvement in his general condition and a weight gain of 5 pounds. A subsequent red-cell count was normal. Fluoroscopy of the gastrointestinal tract after a barium meal and a plain film of the abdomen revealed no abnormality. X-ray films of the hands showed no evidence of Boeck's disease. The tuberculin test was positive. A roentgenogram of the chest in the following October showed no change.

and expectoration. His general condition appeared unchanged, as did the roentgenograms of the chest, through September, 1941. The sputum remained negative for tubercle bacilli.

The patient was readmitted May 4, 1942, because of recent slight hemoptysis. Some edema of the lower extremities of a few weeks' duration was present. He had been taking digitalis for 5 months. Physical examination revealed fair nutrition, slight cyanosis of the lips and nail beds and frequent coughing productive of small amounts of yellowish sputum. No lymph nodes were palpable. The trachea was in the midline. There was slight dullness over the right side of the chest but no rales. On the left there was similar dullness, but coarse moist rales were heard over the upper half. The heart did not appear to be enlarged, and was regular except for occa

sional extra beats; no murmurs were audible. The pulse was 80, the respirations 20, and the blood pressure 140/70. There was no orthopnea. The liver and spleen were not palpable. There was slight edema of the extremities.

Repeated sputum specimens were positive for tubercle bacilli on direct smear. The tuberculin test was positive. The red-cell count was 4,200,000, with 90 per cent hemoglobin (Sahli), and the white-cell count was 8500, with a normal differential count. A blood Hinton test was negative. The urine was normal. A roentgenogram showed cavitation of the upper half of the left lung. The distribution of the miliary lesions seen previously remained unchanged, with some increase in the reaction around the lesions on the left. The cardiac silhouette remained unchanged.

At present the patient is on bed rest. Fever was present up to 100.0°F. during the first 2 weeks after discharge, since when it has been normal except for an occasional rise to 99.0°F.

Although it is appreciated that the recovery of tubercle bacilli from the sputum of this patient does not prove the diagnosis of chronic miliary tuberculosis, the clinical course of the disease makes such a diagnosis extremely likely.

SUMMARY

A probable case of chronic miliary tuberculosis is presented, with a review of the outstanding features of this disease.

MEDICAL PROGRESS

THE SULFONAMIDES*

II. Their Clinical Use

CHARLES A. JANEWAY, M.D.†

BOSTON

IN the first section of this report¹ the basic knowledge about the sulfonamides was reviewed. It was pointed out that their activity depends on an inhibition of the multiplication of virulent bacteria in the tissues, and that this bacteriostatic activity can be nullified specifically by para-aminobenzoic acid in vitro and by pus and necrotic tissue in vivo. The essential facts about the pharmacology of this group of drugs were presented. With this material as a basis, the second section will be devoted to the use of the sulfonamide drugs in clinical practice.†

In order to make this presentation as useful as possible, I have organized it in the form of answers to a series of questions which constantly occur in the practice of medicine. These answers may seem too dogmatic to some, too general to others. They are far from perfect, but represent the principles worked out from clinical experience and from discussions with others interested in the field. Without committing any of my colleagues to agreeing

with me, I should like to admit my debt to the following, from whose ideas and criticisms most of these principles have evolved: Dr. Paul B. Beeson, Dr. John Dingle, Dr. Maxwell Finland, Dr. Chester S. Keefer, Dr. Perrin Long, Dr. Champ Lyons, Dr. J. A. V. Davies and Dr. W. B. Wood, Jr.

I. What are the indications and contraindications for the use of the sulfonamides?

Because of the brilliant therapeutic results achieved with these drugs, there has been an increasing tendency on the part of physicians to administer them to any patient with a fever. If they were harmless drugs, this would merely be intellectually indefensible, but since they are not only powerful but potentially dangerous remedies, it is as wrong to give them without specific indications as it is to deprive a patient of their benefits when he is seriously ill.

INDICATIONS

Adequate Therapy

Infections due to susceptible organisms should be treated with sulfonamides only if they are severe or spreading, because it is only under these circumstances that these drugs are very effective. Thus, a physician should know the etiology of common infections and possess sufficient clinical judgment to realize when an infection is spread-

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual*, Vol. III, 1942 (Springfield, Illinois: Charles C. Thomas Company, 1942. \$5.00).

*From the Medical Clinic, Peter Bent Brigham Hospital, and the Department of Medicine and the Department of Bacteriology and Immunology, Harvard Medical School.

†Assistant professor of pediatrics, Harvard Medical School; visiting physician, Children's Hospital; associate in medicine, Peter Bent Brigham Hospital.

‡In this presentation, the local application of these drugs will not be considered, since this is a strictly surgical problem in which I am neither experienced nor competent.

Four days later, on the 16th day of his illness, the patient was readmitted because of increasing pain, swelling

For the next 8 days the patient made satisfactory progress, receiving physiotherapy for the stiffness of the finger and daily dry sterile dressings. Except for a reddish-blue color of the stump and a tendency for it to throb when dependent, the finger seemed to be doing well. On the 9th day after discharge and on the 38th day of illness, following a 40-minute walk in the cold through heavy snow, the patient developed chilly sensations, malaise, headache and lumbar backache. He was admitted for the third time with a temperature of 103°F. and a white-cell count of 16,900. The finger appeared normal on admission, and a tentative diagnosis of grippe was made. However, 36 hours after admission, the white-cell count was still elevated, the finger stump and adjacent areas of the hand became reddened, warm and tender, red streaks

appeared running up the arm to the axilla, and the lymph nodes of the axilla became tender and palpable. Consequently sulfanilamide therapy was instituted, and because the patient's blood only showed a low titer of op

and 3rd admissions. However, the drug, despite adequate levels and early treatment, did not sterilize the local lesion, perhaps because of the accompanying staphylococcal infection and suppuration. The flare up that oc

son for the strain of hemolytic streptococcus from his finger, he was given 500 cc of blood from a donor found to possess opsonins for this strain. With the combination of these measures and local heat and immobilization, the fever, lymphangitis and lymphadenitis subsided rapidly. He was given full doses of sulfanilamide for 3 days, then gradually decreasing doses, because of an adequate blood level (the fluid intake was poor) for the next 9 days. Following a second immunotransfusion, chemotherapy was discontinued and the patient had no further difficulties, except for some circulatory disturbances in the finger and a moderate anemia, which gradually disappeared.

Comment. This case demonstrates the efficacy of sulfanilamide in controlling the acute invasive manifestations of hemolytic streptococcus infection, as shown by the rapid subsidence of fever and lymphangitis on the 1st

curated at the 3rd admission probably had its origin in a thrombophlebitis of one of the veins in the finger stump. Because the patient had had recurrences and did not tolerate sulfanilamide well, he was given antibody by transfusion from two donors whose blood contained opsonins for his organisms. Chemotherapy was then discontinued without further flare up, but this might have occurred anyway. One must not underestimate the value of the time honored surgical procedures of local heat and immobilization in the control of the lymphangitis, nor of amputation in removing the suppurating focus once localization occurred.

It cannot be emphasized too strongly that the effectiveness of sulfonamide therapy will always be limited to a considerable extent by the accuracy of

the bacteriological diagnosis. The treatment of serious infections is difficult when no such diagnosis has been made and when there is no bacteriological check on the progress of the patient. For that reason, before chemotherapy is instituted, cultures of the local lesion and the blood should be taken if possible, as has been customary with lobar-pneumonia patients before the institution of serum therapy. On the other hand, chemotherapy should never be deferred when it is clearly indicated solely because of a lack of laboratory facilities. Table 1 presents in compact form the types of infection in which the sulfonamides are known to be effective, the type of dosage required, the drug of choice and any accessory therapy that should be given.

There are a few infections which are relatively mild, but which menace the community by their infectiousness or the individual by their tendency to produce serious chronic disability. If such an infection is susceptible to sulfonamide therapy, these drugs are certainly indicated in order to prevent serious end results. In this group belong gonorrhea, trachoma, lymphogranuloma venereum and the majority of urinary-tract infections (Table 1). These are usually mild in their early phases, but potentially serious, and all respond to some degree to chemotherapy.

Three-day Trial of Therapy

If a patient is obviously seriously ill with an infectious disease and the physician cannot make a definite diagnosis, he has no right to withhold sulfonamide therapy. The treatment carries a risk of perhaps 0.2 per cent mortality in competent hands, which is too small to justify the denial of a form of therapy that has wide application to many types of infection, provided the patient is seriously ill. Under such circumstances a three-day trial of the sulfonamides is entirely justified. At the end of this period, a bacteriologic diagnosis may have been made, so that the physician will have some basis for a decision about further chemotherapy. If no response to adequate therapy occurs in three days, there is little sense in continuing a drug that has not influenced the course of the disease.

This situation arises most frequently in cases of puerperal infection. The mortality rate of puerperal sepsis due to hemolytic streptococci used to be about 25 per cent. With the prompt administration of the sulfonamides it has been brought to a very low figure. Every hour's delay in starting treatment seriously decreases the patient's chance of survival, and therefore sulfonamides should be administered as soon as a definite postpartum temperature rise above 101°F. occurs. At the same time cultures of the blood and uterine cavity should be taken. However, the vast majority of cases of

puerperal sepsis are not caused by beta-hemolytic streptococci, but by organisms normally present in or near the genital tract, particularly colon bacilli and anaerobic streptococci. The latter do not respond to the sulfonamides; hence in most cases, after a three-day trial, fever and chills may still be present. By this time cultures should be available. If no organisms such as beta-hemolytic streptococci, virulent staphylococci or *Clostridium welchii* have been found, and adequate chemotherapy has not caused a marked reduction in temperature, it should be discontinued.

Prophylactic Therapy

Animal experimentation has demonstrated that the sulfonamides are frequently even more effective in the prevention of infection than in its cure. For this reason their use as prophylactic agents has frequently been advocated. This is a difficult subject on which to make rules, as the decision usually has to be made in the individual case. It is certain that if enough patients receive the sulfonamides prophylactically, someone is going to die from them. Thus, there is a definite though probably minute risk to life. That this really exists is attested by the death recently reported by Stowell and Button.⁴ Beyond this there is the risk of sensitizing the patient, so that future sulfonamide therapy for more important reasons may produce severe reactions. Against these risks should be balanced the chances of infection and the dangers therefrom. The following are situations in which these drugs should probably be used prophylactically. In general, the prophylactic dose is smaller than the therapeutic dose.

Definite indications include the following: dirty, traumatic wounds; burns; influenza, during an epidemic when complicating bacterial pneumonia is frequently observed; known exposure to gonorrhea; cases of rheumatic or congenital heart disease for twenty-four hours before and seventy-two hours following dental extraction, tonsillectomy or any operative procedure that might permit the entrance of bacteria into the blood stream (in the hope of preventing bacterial endocarditis); and contamination of the peritoneal or pleural cavities.

Questionable indications include the following: the prevention of scarlet fever or hemolytic streptococcus infection in a person with known exposure, for whom the disease would constitute a serious hazard; under certain conditions, as a prophylactic against the activation of rheumatic fever by preventing hemolytic streptococcus infection of the pharynx (the use of the drug under these circumstances must be decided on the merits of the individual case; such prolonged administration as is necessary for good effects may be harm-

ful per se and certainly is not without risk⁴; more evidence is needed on this score⁵); and inlying catheter, that is, patients on constant bladder drainage (this practice is justifiable for a period of a week or so).

CONTRAINDICATIONS

Infections Not Responding to Sulfonamides

Such infections exist, and constitute an important contraindication to the use of these drugs, when a definite diagnosis can be made. When it is known that the therapy will do no good, will only serve to make the patient more uncomfortable, and may complicate his illness, the doctor should have sufficient courage to avoid giving it, even though the family may want to know why the patient is not receiving a sulfonamide drug. Certain diseases in which these drugs have no favorable effect are as follows: "virus" or atypical pneumonia and psittacosis; influenza, in the absence of secondary bacterial infection; common cold; typhoid fever; typhus and Rocky Mountain spotted fever; infections due to neurotropic viruses (poliomyelitis and encephalitis); acute exanthemata in the absence of bacterial infection; infectious mononucleosis, in the absence of secondary infection; puerperal infections due to anaerobic streptococci; urinary-tract infections due to enterococci; toxic manifestations of scarlet fever; diphtheria; and tetanus. In certain other diseases, such as tularemia and brucellosis, the evidence that the sulfonamides do more than produce temporary improvement is scanty, but they probably deserve a trial for several days.

Mild Illness or Localized Infection

One of the truths which was apparent to former physicians who had few specific remedies was that most patients got well if let alone and given a reasonable chance. This simple fact seems to have been forgotten, and there is a growing tendency to replace the therapeutic nihilism of former years with therapeutic overenthusiasm, aided and abetted by the glowing reports of new remedies to be found in popular magazines and the attractive brochures that arrive by the score in each week's mail.

The sulfonamides are not very effective, particularly against organisms like the hemolytic streptococcus, when there is no fever and the inflammatory process is indolent. Thus, attempts to rid the throat of hemolytic streptococci in the absence of symptoms or to treat a mild attack of acute tonsillitis with one of the sulfonamides are usually doomed to failure. The evaluation of treatment in tonsillitis requires great judgment. Although studies have indicated that the sulfonamides have little

effect on the disease,⁶ some observers feel quite confident that its severe complications can be reduced in frequency and successfully combated by chemotherapy. I rarely use the sulfonamides unless the temperature exceeds 102°F. or there is evidence of extension of the infection, such as sinusitis, adenitis or otitis media. On the other hand, in cases of acute nephritis, sulfanilamide has been recommended as a means of diminishing focal streptococcal infection, particularly in the tonsils.⁷ Its main virtue is to reduce the number of bacteria and to make possible the early extirpation of the focus without producing a flare-up. In such cases it should only be used under very close supervision.

Localized infection, associated with the accumulation of pus, is resistant to sulfonamides, because of the inhibitor present in the pus. The drugs are very effective in aiding the localization of spreading infections, but once localization takes place they may have little effect in actually getting rid of bacteria. Thus, in puerperal sepsis, hemolytic streptococci are usually found in the lochia long after sulfonamides have cured the disease. If all the pus can be removed from an abscess, such as an empyema cavity, the sulfonamides may then assist cure without resort to surgery,⁸ but the total removal of pus is often technically impossible by aspiration. A three-day course of chemotherapy starting twelve hours before incision of a severe purulent infection such as a carbuncle, may occasionally be worthwhile in an attempt to prevent metastatic infection from the trauma of operation.

Previous Severe Toxic Reactions to Sulfonamides

These drugs are now being used so extensively that a physician should always ask the patient whether he has had them before starting therapy, and if so, how he tolerated them. If he had a severe reaction, the physician should use a different sulfonamide and proceed with some caution. I believe that intensive chemotherapy with a different sulfonamide drug should be used if the patient is desperately ill. If, however, treatment can be deferred for a short time, he should be given a test dose of 0.5 gm. of the drug. If no untoward symptoms appear in twelve hours, full doses can probably be safely used. Even if a patient has had no reaction to a previous course of sulfonamide therapy, particularly a short one, the physician should be on the alert for toxic reactions during a second course. I recall a patient who developed high fever within twelve hours of the start of a course of sulfathiazole for a urinary tract infection. On careful inquiry it was found that she had received sulfathiazole six months previously. This course had produced sterilization, but since it lasted only four days,

all the drug was excreted before she became sensitive, and hence no reaction occurred at that time. Sensitivity persisted, however, and she developed an accelerated reaction when the drug was readministered six months later.

Acute Rheumatic Fever

Patients with this disease actually become sicker when sulfonamides are given.^{9, 10} The drugs may also be dangerous in certain cases of acute disseminated lupus erythematosus.^{11*}

Leukopenia

At this point, it is worth emphasizing that leukopenia or agranulocytosis is *not* a contraindication to sulfonamide therapy in cases of severe pyogenic infection. In overwhelming pneumococcal, hemolytic streptococcus or staphylococcal infections, the white-cell count may be depressed to levels of less than 1000, with almost complete absence of polymorphonuclear leukocytes. Whenever a physician meets this situation, he should bear in mind the possibility of leukemia. However, this depression of the bone marrow can occur in severe infection. From the standpoint of therapy it is an indication for immediate, intensive chemotherapy, since it is a grave prognostic sign. The circulars on pneumonia therapy issued by the Massachusetts Department of Public Health in years past have stated that leukopenia is an indication for serum therapy and a contraindication to chemotherapy. This, I believe, is entirely wrong. Serum therapy acts only by making possible phagocytosis of pneumococci by leukocytes in the lung and by the reticuloendothelial cells lining the vascular system. The number of circulating polymorphonuclear leukocytes is no indication of their number in the lung lesion, where their action on the pneumococci must take place, but presumably there will be fewer at the spreading margin of the lesion if there are very few in the peripheral blood. Therefore serum therapy is apt to be less effective in such cases. On the other hand, chemotherapy, which attacks the organisms themselves and can destroy pneumococci without the intervention of white blood cells in the pneumonic lung,¹² is the most effective form of treatment, since it stops the multiplication of the organisms, which is responsible for the bone-marrow depression. In such severe cases of pneumonia, combined therapy is probably most effective, so that once intensive chemotherapy is under way, serum should also be used. This of course applies to leukopenia before chemotherapy begins. Leukopenia appearing after chemotherapy has been instituted, when the patient is improving, is usually due to the drug itself.

*Although sulfonamides should not be given for the treatment of rheumatic fever itself, they should not be withheld from rheumatic patients when there is a clear indication, such as septicemia or pneumococcal pneumonia.

II. Which sulfonamide drug should be used?

There are several factors to be weighed in the choice of a sulfonamide drug for the treatment of any particular case. These are the relative efficiency of the different drugs in the particular infection; the previous experience of the patient with sulfonamides; and pharmacological considerations.

The relative efficiency of the different drugs in different types of infection is partially covered by Table 1. In general, sulfanilamide is less potent than the other sulfonamides, except perhaps against Group A hemolytic streptococci, so that it should be used only in infections due to the latter organism or where its high diffusibility and lack of toxicity for the kidney are assets that outweigh its drawbacks. Sulfanilamide is ineffective in pneumonia, and gives comparatively poor results in gonorrhea. There are few bacteriologic reasons for selecting one of the three substituted sulfonamides over the others, except in the case of infections due to staphylococci, Clostridia or gram-negative enteric bacilli, where sulfathiazole seems to have a slight advantage. In general, sulfathiazole and sulfadiazine possess somewhat greater potency than sulfapyridine.

The previous experience of the patient is important, and if he has had toxic reaction to a given drug, the physician should use a different one. This is one of the best reasons for having three different substituted sulfonamide drugs available.

Pharmacological considerations weigh most heavily in the choice of a drug. Neither sulfanilamide nor sulfapyridine should be used routinely, because of the subjective discomfort they produce in the patient, either malaise, headache and anorexia or nausea and vomiting. Sulfathiazole and sulfadiazine are much better tolerated. However, sulfanilamide is recommended in the treatment of acute hemorrhagic nephritis because it rarely injures the kidney. It is useful also for subcutaneous or intrathecal administration, and may be employed to initiate chemotherapy in meningitis because it enters the spinal fluid so readily.

In general, sulfadiazine is the drug of choice in the systemic chemotherapy of all types of infection, with the following possible exceptions:

Urinary tract. Sulfathiazole is potent in small doses against the common organisms causing this type of infection. It is rapidly excreted in the urine in high concentrations and hence gives best results on the smallest dosage.

Gonorrhea. In this disease, sulfathiazole and sulfadiazine give equally good results. It seems worth while, however, to use sulfathiazole and to save sulfadiazine for more serious infections,

when its lack of side effects may be very helpful, because large doses must be given.

Staphylococcal infections. Sulfathiazole is probably the most potent drug (except penicillin,¹³ which unfortunately is not yet generally available) against this stubborn and dangerous organism.

Gas gangrene. Sulfathiazole has a wider range of effectiveness against Clostridia, particularly *Cl. septicum*, than the other sulfonamides.

Anthrax. Sulfathiazole and sulfapyridine are reported as better than the other sulfonamides.¹⁴

In the treatment of meningitis, much has been made of the fact that one drug traverses the blood-brain barrier more readily than another. Sulfathiazole is always present in the spinal fluid in much lower relative concentration than any of the other drugs, whereas the concentration of sulfadiazine in the thecal space rises slowly. For this reason sulfapyridine has been recommended for the treatment of pneumococcal meningitis, and sulfanilamide for hemolytic streptococcus meningitis, since both drugs enter the spinal fluid rapidly. However, success in the treatment of meningitis with sulfathiazole suggests that the concentration of drug in the spinal fluid may not be important except in so far as it reflects its concentration in the tissue spaces. Because treatment in meningitis must frequently be continued for more than ten days, sulfadiazine is probably best, except in staphylococcal infections.

When parenteral administration is used, pharmacological considerations are all-important. For intravenous use, sodium sulfadiazine has great advantages over the sodium salts of sulfathiazole or sulfapyridine. It is excreted much more slowly, so that a patient may be treated by an initial large dose followed by injections of 2 gm. every eight to twelve hours with the maintenance of an effective blood concentration. The rapid excretion of sodium sulfathiazole makes it almost impossible to maintain a satisfactory blood level without producing renal damage, and the same is true to a lesser degree of sodium sulfapyridine. Although both these drugs may be given safely once, repeated doses are dangerous. For subcutaneous administration either 0.5 per cent solutions of the sodium salts of sulfadiazine,* sulfathiazole or sulfapyridine in physiologic saline solution, or else 0.8 per cent sulfanilamide in saline, may be used. The latter is preferable where it is efficacious, since it is rapidly absorbed. When dilute solutions of the sodium salts of the other sulfonamides are given subcutaneously, absorption may be slow and lead to a piling up in the blood after repeated doses.

*Sodium sulfadiazine may be used in concentrations as high as 2 per cent subcutaneously.

For intrathecal use, only 0.8 per cent sulfanilamide should be used, because solutions of the sodium salts are too alkaline; it is doubtful, however, whether intrathecal injection is ever necessary.

III. What is the dose, and how shall it be given?

As has been previously stated, the blood concentration depends on the balance between the rate at which the drug is entering the circulation, usually from the bowel, and the rate at which it is being cleared in the urine. A large initial dose is given, so that the blood level rises rapidly to an effective concentration, and from then on doses are given so as to maintain that concentration by balancing the amount excreted by the kidney. The rate of clearance by the kidney depends on the functional capacity of that organ. The physician should always try to assess renal function by questioning the patient about nocturia and previous nephritis and by examining the urine.

In the presence of normal renal function, the excretion of sulfanilamide is hastened by an increase in the urinary output. With the other sulfonamides, the rate of excretion of the drug is influenced to a much lesser extent by the urinary output. Therefore, when giving sulfanilamide the fluid intake is usually restricted to 2500-3000 cc., whereas with the other drugs fluids are forced, to prevent concentration of the urine and precipitation of the free or conjugated drug in the kidney.

One of the commonest errors is too small dosage. A little sulfonamide treatment is worse than none, because it either has no effect or partially suppresses the infection, whereas the organism has a chance to develop some degree of sulfonamide resistance. It prolongs the period of chemotherapy and thus increases the chances of serious toxic reactions. Once the decision to use chemotherapy is made, the physician should try to get the infection under control as rapidly as possible.

The route of administration should always be oral if possible. This assures slow, steady absorption, and hence a more constant blood level. In patients who are unable to swallow the tablets, they should be pulverized and suspended in a little water, milk or fruit juice. In comatose patients—those with meningitis, for example—a nasal tube can be introduced into the stomach and a suspension of the drug in water given through it.

Parenteral administration is indicated under the following conditions:

For the initial dose in patients with very severe infections. Frequently patients who are very ill are distended, and often nauseated. By giving the initial dose intravenously, an adequate blood level is immediately established, and several hours

are saved, which may be vitally important in bringing the infection under control.* Oral administration of the subsequent doses, if possible, assures continuous absorption and maintenance of an effective level.

In patients who are unable to take oral therapy because of vomiting or for surgical reasons. Ab-

levels following injection, and close attention must be paid to the fluid intake and urinary output.

Table 2 gives the recommendations for dosage in convenient form for reference. The doses given are for an average 150-pound adult. The dosage for children and larger or smaller patients should be adjusted according to weight. In small children,

TABLE 2. Dosage Schedules for Average 150-Pound Adult.

DRUG*	INITIAL DOSE	MAINTENANCE DOSAGE	DESIRED BLOOD LEVEL	FLUID INTAKE	DESIRED URINARY OUTPUT	DOSAGE OF SODIUM BICARBONATE
	gm.†	gm.	mg./100 cc.		cc./24 hr.	
ORAL ADMINISTRATION						
REGULAR DOSAGE FOR GENERAL INFECTIONS

†For conversion to grains, 1 gm. = 15 gr.

‡Initial large dose probably only necessary in dysentery when diarrhea is present; in absence of diarrhea, dose of 0.25-0.3 gm. per kilogram of body weight may be given daily in three or four divided doses (every 6 or 8 hr.).

sorption of these drugs is best in the stomach, so that their administration through a Miller-Abbott tube into the duodenum or jejunum may not be a very reliable method unless carefully controlled by determinations of the blood level. Hence, in severe peritonitis, it is probably best to use parenteral administration.

In patients in whom it is difficult to establish blood levels. In such patients, intravenous doses may be used to supplement oral therapy (Case 2).

It must be emphasized that prolonged intravenous injection of the sodium salts of the substituted sulfonamide drugs carries a high risk of renal complications because of the massive excretion of the drug resulting from the high blood

somewhat larger doses in proportion to body weight are used.

In patients with diminished renal function, the clearance of sulfonamides roughly parallels urea clearance. To establish an adequate level, the initial dose is only reduced to about 80 per cent of the usual one, but subsequent maintenance doses are reduced in proportion to the reduction in renal function, because of the delay in excretion. In such patients, whenever possible, the blood level should be determined frequently, and where facilities are not available, dosage should be reduced as soon as there is a satisfactory therapeutic response.

Very little has been said above concerning the use of the two sulfonamides that have been recommended for strictly intraintestinal chemotherapy, namely, sulfaguanidine¹⁵ and succinyl sulfathiazole or sulfasuxidine.¹⁶ The former is not absorbed to any great extent, but is quite soluble.

*This is very important (Case 6). Enough individuals absorb these drugs irregularly when given by mouth (Case 2) to make it risky to depend on the oral route when starting therapy in a very sick patient.

The latter is probably hydrolyzed in the bowel to sulfathiazole, which is the most potent of the sulfonamide drugs against the coliform organisms and the Clostridia, which make up a large portion of the bacterial flora of the colon. In the lower intestine sulfathiazole is very little absorbed, hence it is largely excluded from the blood. Toxic reactions are apparently more frequent with sulfaguanidine than with sulfasuxidine, perhaps because the former is more readily absorbed. Both drugs are effective in the treatment of bacillary dysentery and of dysentery carriers, and are also effective, when given for about five days preoperatively, in effecting a marked reduction in the bacterial flora of the stools, thereby reducing the likelihood of infection in surgery of the large bowel. In ulcerative colitis, sulfaguanidine has failed to produce much effect, and sulfasuxidine is still on trial. Dosage of either drug should be large, in an effort to saturate the bowel with the drug in solution, which will then be effective wherever it comes in contact with the mucosa. With diarrhea, more frequent and larger doses must be used. If a loop is excluded as with colostomy, the drug must be introduced into the distal loop in order to affect its contents. Prolonged use of either drug should be avoided, since certain essential growth factors, such as biotin, are synthesized to a considerable extent by the bacteria of the bowel.¹⁷

IV. When should the blood level be determined?

The determination of sulfonamide concentrations in the blood and other body fluids has been of enormous value in putting sulfonamide therapy on a rational basis. However, enough is now known of the pharmacology of these drugs to make the determination of blood concentrations superfluous in many cases. When the patient responds promptly to treatment and has no abnormality of renal function, there is no need for determining the blood level. On the other hand, there are some situations in which it should be determined. These are as follows: when a patient does not respond to therapy in twenty-four to thirty-six hours; when a patient has an abnormality of the urinary tract—diminished renal function or incontinence—so that the output cannot be measured; and when parenteral therapy or administration through a stomach or duodenal tube must be used.

V. How long should therapy be continued?

This question is difficult to answer in general terms. It depends on two factors: the rate of elimination of the drug (dependent on the properties of the drug and the renal function) and the properties of the infecting organism. In general, therapy

should be continued until all evidence of infection has disappeared for at least forty-eight hours; in the case of pyogenic infections, until localization has occurred and adequate drainage has been established; or, in certain cases, until sufficient antibody has been developed or administered to the patient to maintain a cure.

Bacterial infections differ in the manner in which recovery takes place. In pneumococcal pneumonia, spontaneous cure is effected by crisis or by lysis, owing to the development of both local and humoral immunity as the result of infection. Administration of serum in sufficient doses will produce an artificial crisis as soon as sufficient antibody is present.¹⁸ The effective sulfonamides likewise produce either a critical or a gradual fall in temperature. This is because pneumococci are readily destroyed, either by phagocytosis if sufficient antibody is present¹⁹ or by autolysis if their growth is inhibited by the sulfonamides.¹² Therefore, once the temperature has become normal, usually forty-eight hours will suffice completely to eradicate the infection, and the drug may be discontinued at the end of this period. On the other hand, hemolytic streptococci are much harder to destroy, and therapy must be continued longer after the temperature has become normal if relapse is to be prevented. In the case of erysipelas or cellulitis, evidences of local infection, such as local redness and edema, may persist after the temperature becomes normal, and chemotherapy should be continued until these disappear. In cases of deep infection, such as mastoiditis and osteomyelitis, it may be impossible to detect evidence of continued infection by any method, and the decision of when to stop the administration of the sulfonamides is very difficult. Such aids as x-ray examination and determination of the sedimentation rate must be used, and therapy should be continued for about two weeks after apparent cure.

Staphylococcal infections are notoriously resistant to all forms of therapy. In such cases, chemotherapy can only be an adjunct, which aids in the localization of the infection and in the clearing of the blood of organisms, and which helps to prevent the development of new foci, particularly in the kidney. Sulfathiazole should be used until adequate localization occurs, the blood is sterile and the focus is draining either spontaneously or as the result of surgical intervention. In meningitis, temperature is a notoriously poor index of recovery, and many patients who do recover will run a fever for a week or two after recovery really occurs. The spinal-fluid findings are most reliable. When all polymorphonuclear leukocytes disappear from the spinal fluid, it is probable that the infection

has been overcome, and the dosage may be reduced over a period of several days. If no signs of recurrence appear, the drug is then discontinued (Case 4).

Chronic infections, such as actinomycosis or subacute bacterial endocarditis, necessitate the continuation of chemotherapy for weeks or months, even though a patient may seem well. In acute infections the aim should be to cure the disease in less than ten days if possible, as serious toxic reactions are much less frequent during this period.

VI. What should be done if there is no response to therapy?

If fever continues despite thirty-six hours of adequate chemotherapy, certain possibilities should be immediately checked.

Incorrect diagnosis. This is perhaps the most frequent reason for therapeutic failure. For example, what is taken to be pneumococcal pneumonia may actually be so-called "atypical" or "virus" pneumonia, pulmonary infarction or typhus fever, none of which respond to chemotherapy. Therefore, the diagnosis should always be checked in such cases, particularly with reference to the bacteriology of the case.

Inadequate blood level. The blood level should be determined, or if this is impossible, and there is no other reason for the failure of therapy, the maintenance dose should either be increased or a single supplementary dose of 2 or 3 gm. of sodium sulfadiazine given intravenously to raise the level promptly (Case 2).*

Presence of pus. This should always be suspected when a patient fails to respond to therapy and continues to run fever. The following case illustrates this very clearly.

CASE 2 (P.B.B.H. M61660 and S69469). The patient, an 18-year-old boy, who had had chronic sinusitis for 5 years, was admitted on the 3rd day of an illness characterized by coryza, cough with blood-streaked sputum and pleuritic pain over the right side of the chest. On admission the temperature was 101.2°F., the pulse 110, the respirations 52, and the white-cell count 19,800. Examination of the chest showed signs of fluid or consolidation on the right, and x-ray films revealed patchy consolidation of the right lower lobe with haziness at the base, interpreted as representing bronchopneumonia with pleurisy. A blood culture was sterile, and a Type 19 pneumococcus was isolated from the sputum.

Despite large doses of sulfadiazine, 5 gm. initially and 1.5 gm. every 4 hours (later increased to 2 gm.), the temperature fluctuated between 101.2 and 103.6°F., the white-cell count rose to 39,000, and signs of fluid, both by physical examination and x-ray study, became increasingly

prominent. The chest was tapped on the 4th and 8th days, and after a long delay, growth of Type 19 pneumococcus was obtained. Therefore, the patient was submitted to closed intercostal drainage on the 8th day, rib resection on the 12th day, and again on the 28th day, before the temperature finally subsided and recovery took place. Sulfadiazine was discontinued after the second operation.

Comment. This case illustrates three points particularly: first, the difficulty experienced in achieving satisfactory blood levels on oral therapy alone in occasional cases; second, the necessity for checking blood levels and looking for pus when there is no therapeutic response; and third, the failure of sulfonamide therapy when there is an accumulation of pus. Despite large doses of sulfadiazine by mouth (5 gm. initially and 1.5 gm. every 4 hours), the blood level was only 3.0 mg. per 100 cc. after 24 hours of therapy. Therefore, the dose was increased to 2 gm. every 4 hours, with a rise in the level to 7.0 mg. per 100 cc. Since this was considered too low, and the infection was not yielding to treatment, an additional 2 gm. of sodium sulfadiazine was given by vein. The next day the level was 11 mg. per 100 cc., but fever continued, and on the following day pus was found in the chest.

Drug fever. Frequently the cause of continued fever in a patient receiving sulfonamide therapy is the drug itself. Of all the problems raised by the introduction of these remedies into clinical medicine, the confusion caused by drug fever is most constantly cropping up. There is no way to be certain when fever is due to the drug. However, if it occurs after the patient has apparently been cured, is accompanied by rash, adenopathy and arthralgia, and is characterized by a paucity of symptoms, relative bradycardia and a normal white-cell count, the diagnosis is simple. Unfortunately, both tachycardia and leukocytosis may occur (Case 6).

Drug fever may be associated with chills, which usually come on soon after the tablets are swallowed, delirium, extreme headache and malaise, or may be practically asymptomatic. The fever may be low grade, septic in type, or high and sustained. It usually begins from the fifth to the twelfth day after treatment is started, and is most confusing when it complicates a disease that responds slowly to therapy, such as staphylococcal infection, so that drug fever is superimposed on the fever due to the infection itself. As already mentioned, if a patient has previously had a course of sulfonamide therapy, and has become sensitized, he may develop drug fever within a few hours after receiving the drug a second time.

The best way to present the problem of drug fever is to cite a number of cases that have occurred in my own experience.

CASE 3 (P.B.B.H. S63445) (Fig. 2). This 26-year-old man was admitted for treatment of an acute urethritis and prostatitis of 5 days' duration. Gram-negative intracellular diplococci were present on smear, and the gonococcus was

*In certain patients an unusually large percentage of the circulating sulfonamide is present in the acetylated form. This is not therapeutically active, nor is it measured by the ordinary blood-level determination. In cases of inadequate level, when good-sized doses have been given, it is worth while, if possible, to determine both the free and the total sulfonamide to check on this possibility.

isolated from the prostatic secretion. He was placed on very large doses of sulfanilamide and did very well, with disappearance of the urethral discharge and of gonococci by culture. However, the blood level rose to 16 mg per 100 cc of sulfanilamide as a result of the large doses,

FIGURE 2. Clinical Course of Case 3

and on the 6th and 7th hospital days the temperature rose, reaching 104°F on the 8th day. With this fever, the patient developed transient pains in the metatarsal region of the right foot, a purplish, blotchy rash and a palpable spleen. The drug was stopped temporarily, but because the temperature did not fall, its administration was resumed on the 9th and 10th days. With this the patient had a shaking chill, the temperature rose to 105°F, the rash became more prominent, and the spleen remained palpable. The first diagnosis had been drug fever, but because of failure of the fever to remit on stopping the drug, the physician felt that the patient probably was developing gonococcal septicemia. When the drug was stopped for a second time and large amounts of fluid were given by mouth and by vein, the temperature soon fell to normal and the rash disappeared.

Comment This is a classic example of severe drug fever, with onset on the 6th day, rash, arthralgia and splenomegaly. The high, flat temperature is quite characteristic of the severe form of intoxication. The chill on readmission of the drug is likewise frequently observed. Nevertheless, the physician in charge of the patient feared that the patient was suffering from an extension of his infection to the blood stream. Since this had occurred in the face of a high blood sulfanilamide level, there would have been no sense in continuing the drug even if the symptoms had thus been correctly interpreted.

CASE 4 (PBBH M61218) This 17-year-old boy was admitted because of drowsiness, headache and vomiting for 24 hours. He was found to have classic signs of meningitis, with a white-cell count of 33,200. A lumbar puncture showed markedly increased pressure and cloudy, yellowish fluid containing 12,500 cells per cubic millimeter, nearly all polymorphonuclear. Culture of the spinal fluid yielded Type I meningococci. In the first 24 hours the patient was given 10 gm of sodium sulfadiazine intravenously because of incessant vomiting, which prevented oral therapy. Thereafter he received 1 gm of sulfadiazine by mouth every 4 hours for 3 days. On this regime the pulse fell from 120 on admission to an average of 60, the temperature from a range of 100–102°F on the 1st day to 99–100°F on the 4th day. Since the blood level was only ranging from 2.7 to 6.6 mg per 100 cc with a spinal fluid level of 7.4 mg per 100 cc, and the patient was complaining of a return of headache the dose was increased to 15 gm every 4 hours. Thereafter the level ranged from 10–13 mg per 100 cc, and he made steady improvement. On the 8th day, the dose was reduced to 1 gm every 4 hours, and on the 10th day to 1 gm every 6 hours. The white-cell count remained normal after the first 2 days, and lumbar punctures revealed a steady decrease in the number of cells. On the 3rd day only about 300 per cubic millimeter were present, of which 30 per cent were lymphocytes, and cultures were negative. On the 8th day there were 37 cells, all but one of which were lymphocytes, and consequently the dose of sulfadiazine was reduced. From the 9th day on, the patient began to run an afternoon fever of 99–100°F for 3 days then rising to 100°F, and from the 15th to the 17th day reaching 101°F. The spinal fluid still showed only a few lymphocytes, but the initial pressure was high (300 mm of water), and the dynamic reactions were rather sluggish. Although it was feared that the patient might be developing a localized focus of infection in the meninges or a partial block because of the increasing fever and lack of symptoms, the drug was discontinued. Within 36 hours the temperature became normal, but the white cell count fell to 4,000 and a typical maculopapular rash of the erythema nodosum type developed over the extremities, which disappeared in 4 days.

Comment This type of low grade septic fever is most confusing. All forms of purulent meningitis are notoriously prone to relapse after sulfonamide therapy, hence the administration of the drug was continued for a long time after all other evidence of infection except fever had disappeared. The prompt subsidence of fever when the drug was discontinued, coupled with the appearance of rash and leukopenia, makes it very likely that the drug was the cause.

CASE 5 (PBBH M58886) (Fig 3) (previously reported by Michael²⁰) This 35-year-old woman developed chills, headache and general malaise with a fever of 101°F 6 days before entry. These symptoms with prostration persisted until 2 days before entry, when she began to feel worse. She developed cough, with the production of large amounts of dark brown sputum, and noticed soreness in her right side. On admission, the temperature was 104°F, the white cell count 10,900, and examination revealed signs of consolidation at the right base. Subsequent bacteriologic studies revealed virulent *Staph aureus* in pure culture in the sputum, and a diagnosis of staphylococcal pneumonia complicating influenza was made. Serologic evidence for recent infection with influenza A virus was obtained from her blood. This type of infection was known to be severe and resistant to therapy, so large doses of sulfadiazine (15 gm every 4 hours) were given and a blood level ranging from 6.4 to 9.8 mg per 100 cc was achieved.

Although the temperature tended downward the first 3 days, thereafter it rose gradually, reaching 105°F on the 12th day, with a pulse of 120 and a white cell count of 7100 (24,000 on the 8th day). With this increase in

temperature, the patient appeared sicker, with signs of consolidation involving more of the right lung and the left base as well (confirmed by x-ray study), and continued to cough with production of large amounts of tan-colored, blood-streaked sputum. However, on the 13th day she appeared slightly better, although the temperature was

and 4 gm. of sodium sulfathiazole and 18,000 units of scarlatinal antitoxin were given by vein. In the next 6 hours two more doses of 2 gm. of sodium sulfathiazole were given intravenously, as well as large amounts of 5 per cent glucose in saline, since the patient had not voided for 12 hours. Within 12 hours after starting intravenous

FIGURE 3. *Clinical Course of Case 5 (reproduced by permission of the Journal of the American Medical Association).*

104°F., and in view of the high, sustained fever, the fall in the white-cell count, and the slight improvement of chest signs, it was decided to discontinue sulfathiazole. The next day the temperature fell precipitously to normal, the white-cell count went down to 4600, and the patient began an uneventful convalescence.

Comment. There seems little doubt that severe drug fever was superimposed on a very severe infection. Where one began and the other ended is impossible to determine. It is not at all impossible that fever, due to the drug, with its potentiation of the bacteriostatic action of the sulfonamides, actually aided this patient in recovering from this severe disease. This case illustrates the rapid recovery from toxic reactions to sulfathiazole when the drug is stopped.

CASE 6. The patient, a 30-year-old white woman, had an uneventful term delivery of her second child. Two days post partum she developed abdominal cramps, anorexia and a fever, which rose rapidly to 105.8°F. with a pulse of 160. The white-cell count was 18,000. She was given 1 gm. of sulfadiazine followed by 2 gm. in 4 hours, and 1 gm. every 4 hours thereafter for the next 24 hours, without any effect on her condition. When seen in consultation, the temperature was 104.8°F., the pulse 160, and the blood pressure 60/40. The patient was acutely ill, breathing with difficulty. There was a diffuse scarlatina-form eruption, and petechiae appeared at any points of trauma. The pulse was thready and rapid, and the abdomen, which was distended, showed marked tenderness in the lower quadrants. A presumptive diagnosis of puerperal sepsis due to scarlatinal hemolytic streptococci was made,

sodium sulfathiazole, the temperature was 99°F. Because of the circulatory collapse, 500 cc. of reconstituted dried plasma was given after the temperature began to fall and the blood pressure rose first to 95/55, when the patient began to void again, and then to 125/80.

A subsequent blood culture, taken before sodium sulfathiazole was given, showed gram-positive diplococci that looked like staphylococci, but were not finally identified. The blood level after the 8 gm. of sodium sulfathiazole was 32 mg. per 100 cc. For the next 17 days sulfathiazole was continued by mouth and the patient made slow progress, despite the development of an acute nephritis, probably due to a combination of sulfathiazole and her infection, and of a spontaneous pneumothorax, which required aspiration of air on repeated occasions. Because she developed some delirium on the 17th day, and there seemed to be no more abdominal tenderness, sulfathiazole was discontinued.

For the next 12 days the patient did very well. However, she then developed pain over the bladder, coming on after voiding. The physician, fearing that she was getting a bladder infection, gave her 1 gm. of sulfathiazole, which was repeated every 4 hours. Despite this, the temperature rose steadily to 104°F., with rapid pulse and respiration. At this time physical examination was negative except for a diffuse bright-red erythema. The white-cell count was 19,000, with 91 per cent polymorphonuclear cells. Questioning revealed that 1 hour after the first dose of sulfathiazole the patient developed epigastric distress and vomited. A diagnosis of drug fever was made, the sulfathiazole was discontinued, and fluids were forced. In 18 hours the temperature had fallen to 102°F. and the

white-cell count to 10,000. Shortly thereafter the temperature rose to 104°F, but the patient felt better. In 36 hours after stopping the drug the temperature became normal and the patient felt entirely well again. From then on, recovery was uneventful.

Comment. This case illustrates many points about chemotherapy. First, the patient was given entirely inadequate doses of sulfadiazine when she was obviously suffering from a fulminating case of puerperal sepsis. Therefore, heroic measures were necessary and she was given massive doses of intravenous sodium sulfathiazole. That these were massive was shown by the blood level of 32 mg per 100 cc after 8 gm, due no doubt to the anuria, which resulted from the circulatory collapse with low blood pressure. As a result of this heroic therapy, the temperature fell to normal in 12 hours. The response of the shock state to plasma, which restored both blood pressure and urinary output, was due to the fact that the infection had already been brought under control. The nephritis that followed, characterized by fixed specific gravity, heavy albuminuria and hematuria with many granular casts consisting of masses of sulfathiazole crystals, was typical of the direct renal injury produced by the drug. The final episode of fever on a second administration of sulfathiazole was a typical accelerated reaction due to previous sensitization. The rash, leukocytosis and high fever were sufficiently like the onset of the infection, however, to make the decision difficult.

CASE 7 (PBBH M61859) (Fig. 4) This 44-year-old Italian bartender, who had been a heavy drinker for years, caught cold and lost "pep" and 20 pounds in weight in

FIGURE 4 Clinical Course of Case 7

the month before admission. Six days before entry he became much worse, with the development of headache, chills, pain in the left side and increased cough with dark blood streaked sputum. Three days before entry he had to take to his bed, because he felt dizzy and exhausted. On admission the temperature was 105.6°F, the pulse 120, the respirations 30, the blood pressure 75/50, and the white-cell count 8300, with a shift to the left. There

were a generalized reddish flush to the skin, muscular rales in both lungs, a little dullness at the right base, abdominal distention and a rapid, weak pulse. On admission a diagnosis of lobar pneumonia was made, and because the patient was so ill, intravenous sodium sulfadiazine followed by oral sulfadiazine was given, and the blood level rose to 14.5 mg per 100 cc. However, since the sputum failed to show pneumococci, a blood culture was negative, and the chest was clear on x-ray examination, the drug was discontinued, and the temperature fell to normal in 3 days with a concomitant rise in blood pressure. An electrocardiogram the day after admission showed intraventricular block, but 5 days later, after intramuscular thiamine therapy, the curves were normal. Therefore, in view of the patient's occupation and his story of loss of strength, a diagnosis of acute beriberi with cardiac manifestations was made in retrospect.

At this point careful questioning of the patient and his physician revealed that he had acquired gonorrhea 2 weeks before entry for which he had been treated with sulfathiazole in full dosage. Shortly before entry he developed fever, and therefore his physician told him to discontinue the drug, but since he became worse he entered the hospital. This made it seem most likely that the patient had severe drug fever on admission. Fortunately, he had been given sulfadiazine, and not sulfathiazole, on entry, or he might have died.

Since it seemed important to know whether the patient was extremely sensitive to the sulfonamides, it was decided to test him with a small dose of each of the drugs. On the 10th hospital day he was given 1 gm (2 tablets) of sulfathiazole. Within an hour the temperature and pulse began to rise, and in 3 hours he had a severe shaking chill lasting 45 minutes. Eight hours later the temperature was 105°F, the pulse 120, and the blood pressure 104/80, and he was acutely uncomfortable, complaining bitterly of headache. The skin was a fiery red and the conjunctivas markedly reddened. High fever continued for 36 hours, with persistence of the rash and a state of circulatory collapse, with the blood pressure about 90/65 most of the time, despite abundant intravenous fluids, 500 cc of plasma, adrenalin and aspirin. An electrocardiogram taken on the 2nd day of the reaction showed paroxysmal right bundle-branch block. On the 4th day after the test dose of sulfathiazole the temperature returned to normal, and on the 6th day the blood pressure returned to its usual level (125/85). The white-cell count rose to 19,800 at the height of the reaction and the next day was 8000, with 92 per cent polymorphonuclear leukocytes. Albumin, red cells and casts were noted in the urine during the reaction. Needless to say, tests were not made with the other sulfonamide drugs.

Comment. This case illustrates both how confusing drug reactions may be to the physician who first sees a patient during the reaction, and also how serious they may be, at least with sulfathiazole. This case seems to show that sulfadiazine may be tolerated by patients exquisitely sensitive to sulfathiazole, since this patient improved rapidly when given sulfadiazine intravenously and orally.

Certainly the best diagnostic criteria for drug fever are the absence of other adequate causes for fever and its appearance five to fourteen days after the start of therapy.

VII. What precautions should be observed in the care of patients receiving sulfonamide therapy?

With the substituted sulfonamides now in common use,¹ only three serious toxic reactions occur with much frequency—fever, leukopenia and oliguria. The temperature should be taken at least twice daily to guard against fever. Leukopenia rarely occurs before the tenth day of treatment, therefore, every effort should be made to end treatment by this time, particularly if the patient is ambulatory. After ten days a close check must be kept on the white-cell count, with determinations every two days. Oliguria is most apt to occur in the period of intensive therapy. The appearance of red cells or granular casts in the urine should serve as a warning that this toxic reaction is imminent, but the best precaution is to observe the urine output in twelve-hour periods. When this falls below 800 cc., fluids should be forced intensively. Sulfathiazole, particularly, may cause complete anuria without the appearance of hematuria. Crystals of the drug mean nothing in a routine urine examination, since these drugs crystallize at room temperatures, but the presence of large numbers of crystals in a freshly voided specimen means that the patient needs either more fluids or a smaller dose.

One point that cannot be emphasized too strongly is that leukopenia or drug fever may occur after the administration of a sulfonamide has been stopped. This is particularly true of sulfadiazine, which is the most slowly excreted, and is to be feared in patients with poor renal function, who rid themselves of any of these drugs very slowly. Sulfathiazole, although it produces toxic reactions more often than does sulfadiazine, is excreted very rapidly, so that if a reaction occurs (except oliguria) it is possible to get rid of the offending drug very quickly. This usually produces prompt recovery from the toxic effect (Case 5). On the other hand, with sulfadiazine several days are needed for its elimination. Case 8 illustrates this serious drawback to its use. Because of the possibility of delayed reactions after the cessation of therapy, the white-cell count and the patient's condition should be checked three and five days after treatment is discontinued. Failure to observe this rule will sooner or later lead to trouble.

CASE 8 (P.B.B.H. M62187) (Fig. 5). This 56-year-old woman with a history of chronic sinusitis developed fever and rapid respirations within a few hours of an operation on the 3rd hospital day. By the next morning the temperature was 103°F., the pulse 110, the respirations 40, and the white-cell count 19,000. A practically pure culture of *Staph. aureus* was obtained from the throat (she could raise no sputum). The patient was cyanotic and

there were signs of consolidation in the right lower lobe. A diagnosis of postoperative pneumonia due to *Staph. aureus* was made, and sulfadiazine was given in large doses, starting on the 5th hospital day. Her temperature fell slowly but steadily, in an entirely satisfactory manner for a patient with a staphylococcal infection. On the 17th day the white-cell count was 9000, the chest signs had cleared, and the patient seemed fairly well. Because the temperature still showed some elevation, the dose of sulfadiazine was reduced, as it was difficult to tell whether this fever was due to the drug or to infection. Since the temperature decreased after this, the drug was discontinued on the 21st day. At this time the white-cell count was 5000 and the temperature normal. Two days later the count was still 5000, the temperature still normal, and the patient was sitting up.

On the 26th day the patient complained of slight sore throat and malaise, developed chills, and by the next day her temperature was over 105°F. and she looked very ill. The white-cell count showed 1250 cells, and on smear no polymorphonuclear leukocytes were seen. This was 6 days after chemotherapy had been discontinued. Despite Pentnucleotide, liver extract, transfusion and vitamins B and C, the patient became steadily worse, the white-cell count failed to rise significantly, fever continued, and she died on the 29th day. Autopsy confirmed the clinical impression that the pneumonia had been cured, and revealed hyperplasia of the bone marrow and an acute enteritis. Post-mortem and two ante-mortem blood cultures were sterile. On the day of death the blood sulfadiazine was 0.79 mg. per 100 cc.

Comment. This case proves in a tragic way that serious toxic reactions may occur a considerable time after the period of chemotherapy. The drug was stopped at a time when there was no reason to suspect that anything was wrong. The white-cell count of 5000, although low, was no lower than is frequently seen when a patient is recovering on sulfonamide therapy and was no lower 2 days later. Perhaps the only sign of impending trouble was the slight unexplained fever after the 15th day; but from the 22nd to the 26th day the patient seemed entirely well. The slow excretion of sulfadiazine and its possible dangers are dramatically illustrated by this case.

The following outline presents a recommended routine in using the sulfonamides:

A. Before administration:

1. Inquire about previous sulfonamide therapy and toxic effects.
2. Assess renal function (possible nocturia, frequency, history of nephritis; urinalysis).
3. Determine hemoglobin level and white-cell count.

B. Administration to ambulatory patients (small doses):

1. Instruct the patient about
 - a. Name of drug.
 - b. Importance of regular doses.
 - c. Importance of adequate fluids and check on volume of urine output.
 - d. Possibility of toxic reaction (report untoward episodes).
 - e. Dangers from slow reaction time in crossing streets, driving car and so forth.

2. Arrange check-up visits at 3, 7 and 10 days; after 10 days the patient should be seen three times a week up to 6 weeks, then weekly so long as the drug is continued.

Check-up should include examination of the mucous membranes for pallor, scleras for icterus

particularly anuria, the renal function is apt to be somewhat impaired, so that the blood level should be watched more closely if the drug is readministered. In all toxic reactions the first move after discontinuing the drug should be the administra-

FIGURE 5. Clinical Course of Case 8.

and skin for rash, a temperature reading and inquiry about malaise, nausea and urinary output. If the last is low, urinalysis should be done. A white-cell count should be made, and if below 6000 a blood smear should be examined.

C. Administration to hospital and bed patients (large doses):

1. Instruct patient or nurse about importance of regular doses.
2. Measure urine output in 12-hour lots; perform a urinalysis daily during the acute phase.
3. Watch the temperature chart.
4. Determine the hemoglobin level weekly and the white-cell count three times a week; examine a smear weekly.
5. Examine patient daily, noting conjunctivas (pallor), skin (rash, purpura), scleras (jaundice), general appearance and behavior.

VIII. What should be done if a toxic reaction occurs?

Acute hemolytic anemia, purpura, hepatitis, high fever, severe rash and leukopenia are indications for immediate cessation of chemotherapy. Oliguria is an indication for omitting one or two doses until an adequate output returns. Following o-

tion of a large amount of fluid (6 liters a day), to hasten the excretion of the sulfonamide. If evidences of infection return with the cessation of chemotherapy, several courses are open to the physician. First, do nothing if the infection is mild. Second, when the infection is severe, use serum or some other type of therapy if it is available. Third, try a different member of sulfonamide group, using a 0.5-gm. trial dose allowing twelve hours to elapse if possible. Adequate figures are available on the frequency with which reactions occur with the other sulfonamides if a toxic reaction occurs with one of them. In some cases it is possible to change from thiadiazole to sulfadiazine (Case 7) without any trouble. In other cases sensitivity of the member of the group seems to be sensitive to some or all of the other

The treatment of agranulocytosis is unsatisfactory. All that can be done is to promote excretion, and to give small injections of Pentnucleon extract, both of which may increase the count either by a stimulatory effect or by replacement.

life, and some observers think that repeated transfusions may depress the bone marrow.

If anuria occurs as a result of sulfonamide therapy, fluids should be forced, and sufficient sodium bicarbonate given to bring the blood-bicarbonate level to normal if it is depressed. If no urine appears as a result of these measures, the ureters should be catheterized and lavage with mildly alkaline solution given as high as possible to dissolve and break up any calculi or precipitates in the ureters and pelvis. This has been more successful with sulfapyridine than with sulfathiazole, which is apt to produce more damage in the kidney itself.

SUMMARY

The following directions are suggested in sulfonamide therapy:

Do not give sulfonamides without good indications.

Do not withhold sulfonamides from desperately ill patients with undiagnosed infections.

If sulfonamide therapy is elected, use adequate doses.

If a patient is very seriously ill, begin with an initial intravenous dose of the sodium salt of the sulfonamide to be used.

Try to cure the patient in the first few days before toxic reactions confuse the issue.

Continue therapy for two or three days after all evidences of active infection subside, or until adequate localization occurs. In meningitis and deep infections involving bone, chemotherapy should be continued longer after apparent cure.

If no response to therapy occurs in two days, check the diagnosis, check the sulfonamide blood level, look for pus, and suspect drug fever.

If no response occurs to adequate therapy in three days, discontinue the drug.

Before administering sulfonamides, try to find out whether the patient has had them and had reactions previously.

Try to assess renal function before deciding on the dosage.

Watch for serious reactions, checking the white-cell count, particularly after ten days, and watching the urine output.

Continue to watch the white-cell count for a week after treatment is stopped.

Force fluids with all drugs but sulfonamide.

After the patient is cured, tell him which sulfonamide drug he has received; if he has had a reaction, instruct him to inform any physician about it before taking sulfonamides again.

**CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITAL**ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor***CASE 28531****PRESENTATION OF CASE**

A twenty-four-year-old nulliparous waitress entered the hospital complaining of abdominal pain of two weeks' duration.

One year before entry the patient had a two weeks' episode of pain in the right and left lower quadrants without chills, fever, nausea or vomiting. She was treated at a community hospital for five days with hot douches, and was apparently cured. She was perfectly well until two weeks before entry when she suddenly experienced throbbing pain in the left lower quadrant of the abdomen. The pain was not severe enough to double her up, but it persisted steadily for six days and then abated somewhat. On the third day of this attack her physician found that she had a temperature of 101°F., and gave her "large white pills," of which she took two every four hours for five days. The drug was stopped because of nausea and vomiting. Four days before entry she had an exacerbation of the pain, which continued until admission. She had had no gastrointestinal or genitourinary symptoms. She had lost about 15 pounds in the previous two months. Her last menstrual period had begun just after the onset of the pain.

She had had the usual childhood diseases. When eight years old she spent a year at a tuberculosis sanatorium because of a "swollen belly." She had several abdominal paracenteses there, and was told that her trouble was due to drinking unpasteurized milk. She had had an appendectomy four years before entry, and an operation for elephantiasis three years before.

She was married when eighteen years old and was separated eighteen months later, but admitted sexual intercourse since then.

Physical examination showed an obese woman with five operative scars, two in each thigh and one in the right lower quadrant. Examination of the heart and lungs was negative. The lower abdomen was prominent, especially on the left, where there was marked tenderness with questionable spasm. There was no tympany, and peri-

stalsis was normal. There was a large rounded lower abdominal mass, which seemed to reach to the umbilicus. The liver was felt one finger-breadth below the right costal margin. The spleen was not palpable. Pelvic examination showed a marital introitus, slight leukorrhea and a normal nulliparous nontender cervix. There was marked tenderness in both vaults, and the fundus could not be felt because of the extreme tenderness. The abdominal mass was tender and did not seem to be connected with the cervix. Rectal examination confirmed the vaginal findings.

The temperature was 100°F., the pulse 64, and the respirations 20. The blood pressure was 96 systolic, 52 diastolic.

Examination of the urine was negative except that the sediment showed 15 to 20 white cells per high-power field; a culture was negative. The blood showed a red-cell count of 4,700,000 with a hemoglobin of 90 per cent, and a white-cell count of 8800 with 76 per cent polymorphonuclears. A cervical smear was negative for gonococci. A blood Hinton test was negative. A tuberculin test (1:100,000) showed a 3-cm. area of erythema at the end of forty-eight hours. An Aschheim-Zondek test was negative.

An abdominal roentgenogram showed a huge soft-tissue mass in the abdomen rising to the level of the first lumbar vertebra and swinging to the left. There was an indefinite area of calcification overlying the left side of the fourth lumbar vertebra, and a similar indistinct area of calcification overlying the left twelfth rib. The areas of calcification appeared to lie peripherally about the mass. An intravenous pyelogram was negative. The mottled calcification seemed to lie over the upper pole of the left kidney but was shown to shift its position relative to the kidney calyces. The bladder film showed a pressure defect that almost obliterated the left half of the bladder. Following a barium enema, the sigmoid was seen to be displaced and plastered against the abdominal mass.

An operation was performed on the third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. GRANTLEY W. TAYLOR: We are concerned with a young woman who presented a large abdominal tumor that had given rise to symptoms of only two weeks' duration.

The past history almost certainly establishes that she had tuberculous peritonitis in childhood, from which she apparently recovered completely. A

laparotomy for appendicitis four years previously would presumably have disclosed persistent disease if it had been present, and might also have revealed the tumor if it had been of long standing. Nothing is offered regarding a possible explanation for the development of elephantiasis in a woman who required operation at the age of twenty-one. In this connection it would be of interest to know her race and nativity. It must be assumed that at some time she suffered from a thrombophlebitis resulting in obliteration of the lymphatic pathways. This may have occurred during her hospitalization in childhood, or possibly following her appendectomy. A year before admission she had an episode of lower abdominal pain, which was probably due to an acute pelvic inflammation.

It is difficult to picture that any of these previous illnesses had any bearing on the tumor. Tuberculosis may give rise to large lymph nodes or inflammatory masses in the abdomen, and these may be associated with calcification, as shown in the x-ray films. But if these had occurred, symptoms would undoubtedly have been present over a longer period, and it would be most unusual for such a large mass to have been present. It is conceivable that a pelvic tumor by pressure could have given rise to the elephantiasis of the thighs, but under these circumstances there would have been numerous other related symptoms. Very large pus tubes may sometimes follow acute pelvic inflammation, but they never achieve the size of this tumor and would undoubtedly present more symptoms in the course of their development.

Other types of inflammatory masses in the abdomen might be mentioned, such as a large hydro-nephrosis or pyonephrosis and the inflammation surrounding diverticulitis of the sigmoid, but there were no other signs and symptoms suggesting the presence of such conditions.

May we have the x-ray films?

DR. JAMES R. LINGLEY: This mass is very large, filling the lower abdomen and extending out to the left flank. It is uniform in density throughout and has sharply defined, smoothly rounded borders without lobulation. It displaces the sigmoid medially but does not involve the bowel.

There are at least six areas of calcification in the abdomen, all of which lie outside the large mass. The four in the upper abdomen have the typical appearance of calcified mesenteric tuberculous lymph nodes. The lower two, however, are unusual in two respects, if they are nodes. First, their positions are wrong, as one lies well out in the right flank and the other lies anteriorly immediately against the anterior abdominal wall.

Secondly, their density is uniform throughout and is much less than one expects in a tuberculous node. Their density and structure suggest the calcification sometimes seen in a certain tumor that occasionally involves the peritoneum extensively.

The film of the chest shows normal lungs, but the diaphragm is elevated, particularly on the right.

DR. TAYLOR: Are the psoas muscles normal?

DR. LINGLEY: Yes; and the kidneys and ureters are not remarkable.

DR. TAYLOR: By x-ray the area of mottled calcification was said to move independently of the kidney, and there were no symptoms referable to the genitourinary or gastrointestinal tract.

An echinococcus cyst must be mentioned as a possibility. Again knowledge of the race and nativity of the patient would be helpful. No specific tests were carried out. Presumably an eosinophilia would have been noted in the blood smear if it had been present.

When we come to consider the various cysts and tumors that may occur in the abdomen, we are at once impressed with the silent character of the tumor prior to the acute episode. The position of the tumor in relation to the side of the bladder, as shown by the x-ray films, argues for a pelvic origin, rather than a tumor involving the liver, spleen or kidney. A cyst of the mesentery or omentum may be present in the pelvis, but does not result in the lower abdominal and vault tenderness. Fibroids and ovarian and paraovarian tumors and cysts are the most likely masses to consider.

Regarding a fibroid tumor, the patient was young, the mass seemed independent of the cervix, and there was no abnormal menstrual history. These do not necessarily rule out fibroid, but tend to. Between solid and cystic ovarian masses, the large size of the tumor argues for a cyst, as does the absence of early symptoms of pressure.

An explanation of the acute episode, with pain, fever and tenderness, must be offered. It seems probable that there had been some torsion or interference with the blood supply to explain these symptoms. In my opinion, the preoperative diagnosis is ovarian cyst, with a torsion of the pedicle. The areas of calcification shown in the x-ray films may have been residuums from the old abdominal tuberculosis, or they may have been areas of calcification in the cyst itself.

DR. LINGLEY: I do not believe that all the calcification is typical of either calcified tuberculous mesenteric nodes or of the tumor I mentioned, namely, papillary cystadenocarcinoma of the ovary. It is quite possible that all the calcification is tuberculous in nature, but in view of the large mass, which is probably a cyst of the ovary, I suggest that the entire picture may have been due to papil-

lary cystadenocarcinoma of the ovary, with extensive psammoma calcification throughout the abdomen. I should be much happier about the latter diagnosis if there were psammoma calcification within the large mass itself.

DR. LOWREY F. DAVENPORT: What about the palpable liver?

DR. TAYLOR: I do not believe that is significant in the presence of obesity.

DR. CLAUDE E. WELCH: I should cast doubt on the past history of elephantiasis, inasmuch as only the thighs were involved.

DR. JOHN H. TALBOTT: I should like to offer one diagnosis that probably does not contribute to the principal difficulty in this patient. The past history of tuberculosis, the presence of hypotension and the roentgenograms of the abdomen showing calcification over the upper pole of the right kidney make one consider Addison's disease. If I had seen only the plain films of the kidney, both anteroposterior and lateral, I should have called it typical of calcified adrenal tissue and highly suggestive of Addison's disease. Of course in consideration of the entire picture one is foolish to make a diagnosis of Addison's disease, but I do believe that the patient is a likely candidate for that disease in the future. She may well develop a lesion of the left adrenal gland in addition to that of the right, which is demonstrable now.

DR. LINGLEY: I agree that there is one small area of calcification in the region of the right adrenal gland, but I doubt that it is in the gland since it moves independently of the kidney, and in the lateral view lies anterior to it.

DR. ALFRED KRANES: Should a mesonephroma be considered?

DR. LINGLEY: I am not familiar with that condition.

DR. DONALD S. KING: Could this be a tuberculous mass?

DR. TAYLOR: I have never seen a tuberculous mass reach this size.

DR. JAMES H. TOWNSEND: I believe that tuberculous salpingitis can sometimes result in the formation of a mass of this magnitude.

CLINICAL DIAGNOSIS

Ovarian cyst.

DR. TAYLOR'S DIAGNOSES

Ovarian tumor, probably a cyst, with torsion.
Old tuberculous peritonitis.

ANATOMICAL DIAGNOSES

(Pseudomucinous cyst of ovary.)
Encapsulated tuberculous peritonitis with calcification.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This patient was operated on by Dr. Burbank, and I shall ask him to describe his findings.

DR. CHARLES B. BURBANK: Our preoperative diagnosis was ovarian cyst. At the time of operation about 2500 cc. of clear yellow fluid under some pressure was found free in the peritoneal cavity. The entire lower abdomen was filled with a large cystic mass, which was adherent to the anterior abdominal wall at the level of the symphysis pubis and also to the right iliac fossa. On the other side it extended almost to the left iliac fossa. Its upper border was at the level of the umbilicus. It had pushed the small intestine forward, and many coils of the ileum were adherent to its anterior and lateral walls and also to each other. It was impossible to enter the pelvis or to identify any of the pelvic organs. Lying just below the peritoneum at the upper end of the incision was a separate mass, measuring 5 by 4 by 2 cm., with a yellow surface. It was soft in consistence and when opened contained white material suggestive of tooth paste. This was totally excised.

Since it was obviously impossible to free up the large cyst, the wisest procedure appeared to be to drain it through the abdominal wall. When an incision was made into it, a large amount of clear fluid was evacuated. A segment of the wall was removed. The inner surface of the cyst was smooth. It was my impression that it was a pseudomucinous cyst, presumably of the right ovary.

DR. MALLORY: In none of the material submitted to the laboratory could we positively identify the cyst as ovarian in origin. However, I think Dr. Burbank's impression can be accepted with reasonable confidence. The smaller mass proved to be an encapsulated mass of semicaseous exudate with active tubercle formation in some portions of its wall and many foci of calcification, 50 to 200 mm. in diameter, in other areas. Many of these were not larger than psammoma bodies, so it is natural that the x-ray picture should have suggested an ovarian papillary cystadenoma to Dr. Lingley.

CASE 28532

PRESENTATION OF CASE

A twenty-one-year-old girl entered the hospital complaining of chills and fever of two and a half weeks' duration.

At nine months of age the patient had been seen at another hospital because of fever and vomiting. The outstanding and relevant findings at this time

were a temperature of 103°F., a pulse of 190 and a respiratory rate of 60. The heart was markedly enlarged to the left with a blowing systolic murmur all over the precordium, but heard best at the apex and transmitted to the back; the enlargement was verified by x-ray examination. At the end of a month the heart had decreased in size, the left border being only 6.5 cm. from the mid-sternal line, with the apex in the fifth interspace. She was discharged two days later with a normal temperature and respirations, but the cardiac murmur had persisted. The patient was readmitted to the above institution two months later with a temperature of 102°F., and a pulse of 150. The same cardiac findings were recorded, the left heart border varying from 8.5 to 9.5 cm. from the mid-sternal line. No significant signs were noted in the lungs, nor was there clubbing of the fingers. During the next two years the patient was examined in the outpatient department of the same hospital at infrequent intervals. The same cardiac abnormalities were noted, and during this period she suffered from urticaria, nasopharyngitis and tonsillitis, the last of these being eliminated by an adenotonsillectomy.

At the age of sixteen, the patient was first seen in the Cardiac Clinic of the Out Patient Department of this hospital, and she continued her visits until the time of admission. No history of rheumatic fever could ever be obtained, and the patient denied having had sore throats, joint pain, chorea, fever, nosebleeds, dyspnea and cardiac arrhythmia, although she suffered from about three head colds each year. The following is a summary of the findings during this period. The patient's appearance was always rather delicate and sickly. The heart was markedly enlarged, the impulse heaving, without a palpable thrill, and the rhythm regular at a rate averaging 100. The sounds were tumultuous, with a loud systolic murmur at the apex replacing the first sound and transmitted to the left lung base. During these years an apical mid-diastolic murmur was thought to be present by some examiners, usually brought out by exercise. The blood pressure averaged 95 systolic, 75 diastolic. Occasionally rhonchi were heard at the lung bases, but at no time were there subcutaneous nodules, clubbing of the fingers or a palpable spleen; a tendency to cyanosis after exercise was very questionable. Three years before admission an x-ray film of the chest showed a heart that was grossly abnormal in shape, with an unusually prominent left upper border. The aorta was small, and the pulmonary vessels dilated. The peripheral lung fields were clear, and the diaphragm was low. Another x-ray examination two years later showed that the heart was enlarged to

the left as well as in the anteroposterior diameter, with a questionable enlargement of the left auricle. The pulmonary conus was prominent, and the hilar vessels and vessels within the lung parenchyma were wider than usual. Fluoroscopy was performed six months before admission and showed enlargement of both the right and left ventricles, with a cardiothoracic ratio of 12:19. The pulmonary conus was enlarged, and a considerable degree of pulsation was seen in the pulmonary arteries. There was no significant enlargement of the auricles. An electrocardiogram at this time showed normal rhythm, a rate of 90 and a PR interval of 0.19 second. T₃ was flat; the QRS voltage was unusually high in Leads 2 and 3, and its amplitude widened to 0.12 second. There was no abnormal axis deviation.

During all this time the patient led a quiet life and remained fairly well, although she entered the hospital for six days on one occasion suffering from severe gingivitis, which cleared readily on treatment.

Two and a half weeks before entry the patient "caught cold"; the onset was accompanied by malaise, anorexia, a persistent cough and chills, and was followed by a low-grade fever. She went to bed and during the next three days had several more chills; at the end of this period, however, the temperature fell to normal and she felt better. The patient resumed her usual activities, but one week before admission a severe chill occurred, which was followed by a temperature varying from 99 to 104°F. In bed again, she suffered from a series of shaking chills with occasional night sweats, and thirty-six hours before entry, at four o'clock in the morning, a severe chest pain awakened her from sleep. This pain was sharp, located in the right chest posteriorly, was aggravated by deep breathing and coughing, gradually increased, but was relieved somewhat by hot packs.

The patient's mother had had rheumatic fever and tuberculosis, and one sister had tuberculosis of the spine.

On examination, the patient was thin, poorly developed and appeared chronically ill, with pale, shiny skin, slight mucous-membrane cyanosis, slight clubbing of the fingers with floating nails and a definite increase in the volume of the jugular pulse. Examination of the head and neck was negative. The lungs were clear. The heart was enlarged, the border being 1.5 cm. to the right of the midsternal line with the apex palpable at the anterior axillary line in the sixth intercostal space. The apex impulse was rapid, regular and forceful; no thrills could be felt. There were two low-pitched murmurs at the apex,—a loud systolic and a rumbling diastolic,—the former being

transmitted to the left lung base. In addition, a high-pitched and loud systolic and a short mid-diastolic murmur were heard just to the left of the lower sternum. These last two murmurs were rather distinctive, but could not be separated definitely from those at the apex. The liver was just palpable, and the spleen easily palpable. Vaginal and rectal examinations were negative.

The blood pressure was 95 systolic, 65 diastolic. The temperature varied between 99 and 105°F. The pulse averaged 100, and the respirations 27.

Examination of the urine was negative. The blood showed a red-cell count of 4,300,000 with a hemoglobin of 13 gm. and a white-cell count varying between 9000 and 18,000, of which 75 per cent were polymorphonuclear leukocytes. Repeated blood cultures yielded Type 6 pneumococci. The nonprotein nitrogen of the blood serum was 26 mg. per 100 cc. The blood Hinton reaction was negative. The stools were normal.

An electrocardiogram showed a normal rhythm with a rate of 115 and a PR interval of 0.20 second. The QRS complex in Leads 2 and 3 was M shaped and low.

An x-ray film of the chest showed gross cardiac enlargement, apparently in the region of the right ventricle and pulmonary artery. Also, there was slight dilatation of both auricles. The aorta was unusually small, whereas the pulmonary vascular shadows were increased in number and size. There were no areas of consolidation in the lungs, and no fluid at the bases. Fluoroscopically, a hilar "dance" was noticed.

Throughout the patient's illness chemotherapy was used, starting with sulfadiazine, which reached a blood level averaging 12 mg. per 100 cc. However, by the thirteenth hospital day, this level had climbed to 21.2 mg. so the drug was discontinued, and the next day the concentration dropped to 15.9 mg. During the last few days of life a shift from sulfadiazine to sulfathiazole was made because the patient had failed to respond to the former drug.

The first few days of hospitalization were without incident, but six days after admission the patient developed a headache, but remained clear and co-operative. Examination showed a widely dilated left pupil, which failed to react, and a third-nerve paralysis on the left, the patient being unable to open the eyelid. A lumbar puncture revealed no abnormalities. She was given 100,000 units of Type 6 antipneumococcus rabbit serum intravenously in four hours, after a negative Francis test. The next day an additional 60,000 units was administered. Four days later the patient developed slight weakness of the seventh left cranial nerve, with a slightly stiff neck and a pos-

itive Kernig sign. Two weeks after admission, pain on respiration developed in the right lower chest anteriorly, with slight cough and dyspnea but no sputum. Examination revealed a few rales and a slight rub low in the right axilla at the end of inspiration. Death occurred on the eighteenth hospital day after an increase in cyanosis and the development of puffiness of the face and moist rales bilaterally. Bronchovesicular breathing with increased whispered voice sounds was heard over an area 4 cm. in diameter at the left lung base.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD F. BLAND: First I should like to ask Dr. Sullivan to comment on the Francis test and its significance.

DR. EUGENE R. SULLIVAN: The Francis test depends on the reaction between the type-specific soluble carbohydrate extracted from the capsule of the pneumococcus and its corresponding antiserum. By injecting intradermally a small amount of the specific carbohydrate (in this case, Type 6), one can test for the presence in the blood of Type 6 pneumococcus antibodies, either of natural development or artificially administered. A positive skin reaction is frequently used as a guide to indicate that enough antiserum has been given.

DR. BLAND: There are two diagnostic problems presented by this case: the answer to the first is evident, but that to the second is difficult.

In connection with the first, the clinical course indicates clearly that this patient succumbed to a pneumococcal septicemia associated with acute bacterial endocarditis superimposed upon previously existing heart disease and complicated by pulmonary infarcts (presumably septic) and by either a metastatic brain abscess or meningitis—probably a combination of the two. A special feature of the embolic phenomena will be commented on later, since it may prove helpful in trying to unravel the second, and more difficult, feature of the case—namely, the underlying type of cardiac disease and especially the structural defects present within the heart.

Any patient in the vicinity of Boston with chronic heart disease in this age group deserves, first, a most careful scrutiny for evidence of rheumatic heart disease, since in this part of the world rheumatic fever is responsible for more than 95 per cent of the crippled hearts in young people. However, I do not believe in this case we have sufficient evidence to consider seriously this etiologic factor. In the first place, the existence of heart disease was recognized at the age of nine months. This is unusually early for the onset of rheumatic fever, although rare cases have been recorded even

in infancy. The youngest patient I have personally observed with rheumatic fever was fourteen months old. The absence of an illness recognizable as rheumatic fever in this patient is only moderately helpful in a negative direction. Of considerably more importance in excluding a rheumatic factor, I believe, are the physical signs, which are not in accord with the more or less well-defined pattern presented by chronic rheumatic scarring of either the mitral or of the aortic valve, and the appearance of the electrocardiogram, which in this instance is particularly suggestive, not of rheumatic heart disease, but of a congenital cardiovascular defect. On these grounds I am therefore willing to discard rheumatic heart disease from further consideration.

I believe we are concerned with a congenital defect in the heart, possibly a combination of such defects. The problem is to name the condition, for we no longer consider it adequate to dismiss such cases with the broadly inclusive term of "congenital heart disease." Experience has shown that an accurate structural diagnosis is possible in the majority of those who survive the first few months of life. A definitive diagnosis in these cases is of considerably more than academic interest for it determines within limits the prognosis, and in an occasional case leads to corrective surgery.

May we have an interpretation of the x-ray films at this point? I notice from the dates that the films submitted are those taken approximately six months before death, when the patient was in relatively good health. The films taken during the final illness are, unfortunately, not available.

DR. JAMES R. LINGLEY: The films taken six months before death show clear lung fields. The heart shadow is grossly abnormal in size and shape. The enlargement is predominantly ventricular, and it appears to affect the right side more than the left. The aorta is hypoplastic as shown by the absence of the curve of the ascending portion along the right upper mediastinum and by the inconspicuous knob. The pulmonary conus is very prominent, and the pulmonary artery is dilated. There is also dilatation of the vascular shadows throughout both lungs, and fluoroscopically a hilar "dance" was demonstrated. So far as I know, this occurs only in congenital heart disease, and most commonly in association with a patent ductus arteriosus or an interauricular septal defect.

DR. BLAND: To me these films indicate primarily three things: prominence of both the right and left ventricles—this is supported by the absence of either right-axis or left-axis deviation in the electrocardiogram and hence relatively little disproportion between the two ventricles; little or no enlargement of the auricles; and a striking in-

crease in the amount of blood in the pulmonary circulation.

These findings suggest a shunt within (or near) the heart. If my major premise is correct, namely, that we are dealing with a congenital heart, then the absence of cyanosis (except of slight extent terminally) indicates that the shunt involves a flow of blood from the left (arterial) to the right (venous) side of the heart. This in turn would explain the dense vascular shadows in the lung roots, and the later pulmonary signs (infarcts).

In regard to the location of the shunt, there are three possibilities. The first is a patent ductus arteriosus, which I am inclined quickly to exclude because of the absence of the characteristic physical signs and no widening of the systemic pulse pressure. The second is a large interauricular septal defect, which with some hesitation I am also willing to discard, at least as the major anomaly, largely because of the absence of x-ray evidence of right auricular enlargement, and also because of the absence of right-axis deviation in the electrocardiogram. The third possibility, a defective interventricular septum, seems to me by far the most likely diagnosis. To be sure the murmurs described do not accord with the classic midsternal systolic murmur accompanying septal defects that are small, that is, less than 1 cm. in diameter. In this case, however, I should expect a large defect to be present because of the cardiac enlargement, the large amount of blood in the pulmonary circulation, and especially the appearance of the electrocardiogram. The last, as you recall, showed a wide amplitude of the QRS complexes in Leads 2 and 3, with unusually prominent and deep S waves together with a slight degree of intraventricular block. In fact, this electrocardiogram is so strikingly similar to that of a boy with a single ventricle whom we studied in this hospital about ten years ago that I am tempted to suggest that rare possibility in this case.

A word remains to be said about the final illness. Patients with congenital defects, especially of the interventricular septum, frequently succumb to superimposed bacterial endocarditis, most often subacute in nature and caused by *Streptococcus viridans*. Less often this infection is due to *Str. haemolyticus*, *Staphylococcus aureus* or a pneumococcus, in that order of frequency, and if so, the course is more acute—two to six weeks. Since the abnormal flow of blood is from left to right in the heart, it should be remembered, emboli are swept backward into the pulmonary circulation, with resulting infarction in the lungs. This is my interpretation of the intermittent acute pulmonary symptoms of which this patient com-

plained and which toward the end were associated with signs of pulmonary consolidation

How are we to explain the cerebral symptoms? Was this a paradoxical embolus toward the end as the pressure gradient between the two ventricles declined, and the pulmonary circulation became more engorged? Or was there in addition a complicating interauricular septal defect that permitted passage of an embolus under similar circumstances? I do not know, but I think a more likely explanation is extension of the bacterial vegetations into the left side of the heart with resultant peripheral emboli. Perhaps there was meningitis secondary to the septicemia per se.

To summarize briefly, I believe this patient had congenital heart disease—a large interventricular septal defect (essentially a single ventricle)—and acute bacterial endocarditis, predominantly in the right side of the heart, involving the defect and almost certainly the adjacent cusps of the tricuspid valve with septic infarcts in the lungs and probably in the brain, associated with meningitis. Dr Heyl, would you comment on the neurologic aspects of the case?

DR HENRY L. HEYL: The significance of a unilateral third nerve palsy is often obscure. It could represent a local lesion in the region of the nucleus, such as infarct, abscess or thrombosis. It could be caused by a local meningitis secondary to the bacteremia. It might even be due to a contralateral mass pushing the brain to the left and catching the nerve between the tentorium and the cerebral peduncle. Of all these, the presence of a local meningitis seems most likely in this case, with or without a small, precisely placed infarct in the region of the third nerve nucleus. The appearance of the seventh nerve palsy may have represented a spread of infection or a repetition of infarction, however, it was more likely a nonspecific cerebral manifestation of terminal disease.

DR JAMES H. TOWNSEND: Would you comment on what you consider the most important signs in patent ductus arteriosus?

DR BLAND: A continuous murmur to the left of the upper sternum usually accompanied by a systolic thrill.

DR S. PETER SARRIS: Can pulmonary regurgitation give a hilar dance?

DR BLAND: Yes, but organic pulmonary regurgitation is extremely rare.

CLINICAL DIAGNOSES

Congenital heart disease (? cor triloculare)
Acute bacterial endocarditis (Type 6 pneumococcus)
Acute meningitis (Type 6 pneumococcus)
Bronchopneumonia

DR BLAND'S DIAGNOSES

Congenital heart disease: interventricular septal defect large (? cor triloculare, with a single ventricle)
Acute bacterial endocarditis (Type 6 pneumococcus, involving septal defect and tricuspid valve)
Infarcts, septic lungs and ? brain meningitis

ANATOMICAL DIAGNOSES

Congenital heart disease: interventricular septal defect, very large (cor triloculare batriatum)
Bacterial endocarditis, subacute, tricuspid (Type 6 pneumococcus)
Endocarditis, chronic, tricuspid
Pulmonary embolism, multiple
Dilatation of pulmonary artery
Hypoplasia of aorta
Cardiac hypertrophy
Pulmonary edema
Hydrothorax
Infarcts of lung, spleen and kidneys
Hypertrophic pulmonary osteoarthropathy, minimal

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY: The first suggestion that this patient was suffering from congenital heart disease came from Dr Schatzki, following x-ray examination. Before that time everyone had accepted the diagnosis of mitral stenosis. When the cardiologists were called in consultation they, too, were inclined to congenital heart disease. Dr Ashton Graybiel favoring an interatrial septal defect and Dr P. D. White an interventricular one. In fact Dr White, whose note I shall read, hit the nail directly on the head like Dr Bland by suggesting a trilobulate heart with a single ventricle.

This is an acute type of bacterial endocarditis not responding to chemotherapy as yet. The problem concerns the diagnosis of the underlying heart disease. Certainly the findings do not fit any of the ordinary types of congenital heart defects such as patent ductus, ventricular septal defect, auricular septal defect, coarctation of the aorta, tetralogy of Fallot and aortic or subaortic stenosis and yet the early age at which the heart disease was discovered (nine months), the bizarre electrocardiogram (wide QRS waves with very prominent R and S deflections in Leads 2 and 3) and odd x-ray picture support the diagnosis of congenital heart disease. Because of the similarity in certain respects (electrocardiographic murmurs and terminal cyanosis) with our one case of trilobulate heart with a single ventricle I should hazard that diagnosis here. The next best bet is a very unusual rheumatic heart with early development of mitral and perhaps also

The first health unit was opened on Blossom Street in 1916. Dr. Wilinsky, who was already an official of the Boston Health Department in charge of the West End Health District, became the director of the unit, and under his able leadership the project soon proved its value.

Although improved in succeeding years, the quarters of the unit, consisting of a hall that had been used for a ward-room and subsequently as a gymnasium, were totally inadequate, according to present-day standards. Furthermore, expansion of the program by the provision of additional units in congested districts was slow on account of the expense and of the opposition of those who were not sympathetic.

Dr. Wilinsky always stressed the point that the units should not duplicate the work of clinics. On the contrary, he believed that they should decentralize the services of the Health Department and make them more readily available to the public. Year after year, confidently and persistently, he explained the health-unit idea and gained additional supporters. He convinced the Mayor's Office, the Advisory Board of the Health Commissioner, the Boston Health League and several medical and other groups that had opposed him at first. But it was not until the trustees of the George Robert White Fund became interested in the program that fine buildings were constructed to house the units. The projected series of units was finally completed in 1933.

The fame of the health units has spread far and wide. They have been visited and admired not only by health officials from other American cities, but also by leading sanitarians from many of the countries of Europe. It can truly be said that from Dr. Wilinsky, more than from any other, came the vision, the energy and the enthusiasm that gave Boston these health units. With the passing years will come perspective by which their value can be accurately appraised. It seems likely, however, that they will ultimately be regarded as one of the greatest contributions of this generation to public-health administration.

MEDICAL EPONYM

EUSTACE SMITH SIGN

This sign, although not unanimously accepted as valid, is still frequently referred to. It was described by Dr. Eustace Smith (1835-1914), physician of the East London Children's Hospital, in a communication, entitled "On the Diagnosis of Enlarged Bronchial Glands in Children" (*Lancet*, 2: 240, 1875). He writes:

The symptoms by which enlargement of the bronchial glands can be distinguished . . . are all pressure signs due to the encroachment of the swollen body upon the parts around. . . . At an earlier period, and before the enlargement has become . . . great, . . . much assistance can be gained from the following experiment. If the child be made to bend back the head so that his face becomes almost horizontal and the eyes look straight upwards at the ceiling above him, a venous hum, varying in intensity according to the size of the diseased glands, is heard with the stethoscope placed upon the upper bone of the sternum. As the chin is now slowly depressed, the hum becomes less loudly audible, and ceases some time before the head is brought back again into the ordinary position.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1941

SURGICAL COMPLICATIONS

Of the 10 deaths that resulted from surgical complications, 5 were due to appendicitis and peritonitis, 3 followed intestinal obstruction, and 2 were associated with ovarian cysts. There were two autopsies.

Of the 5 cases complicated by appendicitis and peritonitis, the first occurred in a primipara who at three months was operated on for symptoms of acute appendicitis of unstated duration. At operation the appendix was found to be ruptured and there was free pus in the abdominal cavity, because of which drains were left in the abdomen. General peritonitis resulted, and death occurred on the fifth postoperative day. The chief question is how long this patient suffered before operation. Too often the symptoms of appendicitis are not recognized, because of pregnancy, until rupture has occurred. Whether or not pregnancy exists, appendicitis should be treated surgically as soon as a diagnosis has been made, and the sooner an operation is performed, the less chance there is of fatal peritonitis.

The second patient, who had had one previous pregnancy, had what were described as "bearing-down pains" in the abdomen and nausea at five months. These complaints continued for two days, at the end of which time a threatened abortion was diagnosed. The following day the patient had a temperature of 100°F. and a rigid abdomen. A diagnosis of acute appendicitis was made, the patient was hospitalized, an unruptured appendix was removed, and the abdomen was drained. She was transfused two days later, and the following morning a spontaneous abortion occurred. Death followed in two days from peritonitis. It is possible that if a diagnosis of acute appendicitis had been made at the onset of this illness and operation performed immediately, this fatality might have been averted. The abortion following operation was probably due to the infection rather than to the operation itself. It must always be borne in mind that a pregnant woman may have acute appendicitis and that this condition demands immediate operation—the sooner this treatment is carried out, the surer one may be of recovery.

The third case occurred in a primipara who had been seen prenatally and who, at about five and a half months, complained of pain in her back, which followed a fall. The temperature and pulse were said to be normal. The following morning she was seen because of pain in the abdomen and a white-cell count of 25,000. An acute gangrenous appendix was removed; three days after the operation the patient miscarried, and she died of peritonitis on the eleventh postoperative day. It is, of course, quite likely that the pain in the back of which the patient complained, regardless of a normal temperature and pulse, was really due to a retrocecal appendix. It is unlikely in an adult that, with a white-cell count elevated to 25,000 and a gangrenous appendix, there were only a few hours of symptomatology. This again emphasizes the importance of early diagnosis of appendicitis.

The fourth patient was a primipara who was delivered at term of a normal living infant but died on the fifth post-partum day of peritonitis. No operation was performed, but an autopsy revealed a perforated gangrenous retrocecal appendix and peritonitis. This was a most regrettable death.

The fifth case was that of a patient who had had six previous pregnancies and was operated on at approximately the fifth month for what was thought to be an ovarian cyst. Operation revealed an acutely inflamed retrocecal appendix, which was removed. The patient's convalescence was febrile and associated with vomiting and distention. Ten days after the first operation the abdomen was again opened and a gangrenous cecum and pelvic abscess were found. The patient went

steadily downhill and died two days after the second operation. The surgery in this case cannot be commended. Undoubtedly this was an entirely unnecessary death.

Three deaths were associated with intestinal obstruction. The first case was that of a patient, six months along in her second pregnancy, who became acutely ill with nausea, vomiting and abdominal pain. A diagnosis of intestinal grippé was made; the vomiting persisted, and the patient was hospitalized. Two days later labor started spontaneously and a dead fetus was delivered normally. She underwent no operation and died twelve hours after delivery. Undoubtedly this was a case of intestinal obstruction, and operation should have been performed early. Persistent vomiting and abdominal pain in a patient who is pregnant and without symptoms of toxemia should be considered indicative of an acute abdomen. The only way to operate successfully on acute intestinal obstruction is to operate early. This patient did not receive the most intelligent treatment.

The second patient, who had had a previous cesarean section, was again delivered by section in her third pregnancy. She was known to have a hernia in the old scar, and following operation she had attacks of abdominal pain, nausea and vomiting, for which Levine-tube treatment was instituted without relief. Death occurred on the fifth post-partum day, and autopsy revealed incarcerated loops of small intestine in the hernia. There is no excuse for this fatality. The diagnosis of intestinal obstruction should have been made earlier, and immediate operation should have been performed.

Of the third case in this group the history is inadequate. The patient was apparently delivered normally but died from peritonitis following intestinal obstruction, which was due to gangrene of the rectum.

Of the 2 deaths associated with ovarian cyst, the first occurred in a patient who was hospitalized because of evidence of salpingitis; in spite of a spiking temperature and a white-cell count of 24,000 she left the hospital against advice. Operation was performed one month later because of continued pain; a pyosalpinx was discovered, and considerable pus was evacuated. A right ovarian cyst was also found, which ruptured on attempted removal. In addition, there was a three to four months' pregnancy, which had not been suspected. Death occurred from peritonitis. Pregnancy occurring in a patient suffering from acute salpingitis is certainly very unusual. It is probable that, had the salpingitis been treated conservatively and operation deferred, this fatality would not have taken place.

The second patient, who was curetted for a spontaneous abortion at about two months, developed sudden pain in the abdomen as she was about to be discharged from the hospital. Immediate operation revealed internal abdominal hemorrhage. It is said that the hemorrhage came from a ruptured ovarian cyst on the right. The patient died within thirty-six hours of the operation from continued bleeding associated with oozing from the abdominal wall. It is probable that a ruptured ectopic pregnancy was the cause of the intra-abdominal bleeding.

The chief lesson to be deduced from these surgical deaths is, Pregnancy should never be allowed to obscure a proper diagnosis. Consultation should be held in any questionable case of abdominal symptomatology. Early diagnosis means early operation; early operation, in contrast to deferred operation, means recovery rather than fatality. The patient who is reported to have had salpingitis should in all probability never have been operated on. The questionable case of ruptured extra-uterine pregnancy represents a fatality due to incorrect diagnosis.

SECRETARY'S OFFICE

The following letter appears to be of sufficient general interest and importance to warrant publication.

MICHAEL A. TIGHE, *Secretary*

* * *

Dear Dr. Tighe:

During the next twelve months 276 nurses are to be drawn from New England every month to enter the military services, which means that a total of 3312 nurses under forty years of age will be lost from our civilian services in this area by the end of the year; 140 a month will be drawn from Massachusetts alone. This is a large number, and in order to reach it, almost every eligible nurse who can possibly go will have to volunteer. If we can retain enough young instructors and supervisors to keep up the preparation of new nurses, we shall be very fortunate. For almost every other position, the nurses ineligible for military service will have to fill in. The understanding and support of physicians in encouraging the eligible young nurse to answer the call (which is still voluntary) is much needed.

This will leave many vacancies in hospitals to be filled by *increased classes of student nurses*, which is one of the essential ways of keeping up hospital standards of care. Recruitment of student nurses for schools of nursing grows constantly more difficult, in competition with the WAVES and WAACs and well-paying industrial jobs. Our midyear (February, 1943) classes in Massachusetts alone need 1100 more applicants to meet the quotas set. Connecticut needs 351; Rhode Island 71; Maine 302; New Hampshire 148; Vermont 127; according to quotas.

The supply of student nurses is the concern of physicians as well as nurses. Studies have shown that family physicians have marked influence in directing young women toward nursing as a career. That is why we are

addressing this letter to you, hoping that it may reach many physicians who will give this campaign for student nurses their active support.

Several questions are inevitable, which the following may answer:

1. *Where can the applicant find out about accredited schools of nursing?*

From the secretary of the state Nursing Council for War Service: in Massachusetts at 420 Boylston Street, Boston; in Connecticut at 252 Asylum Street, Hartford; in Rhode Island at 42 Weybosset Street, Providence; in Maine at 54 Saunders Street, Portland; in New Hampshire at Elliot Community Hospital, Keene; and in Vermont at 3 Nelson Street, Montpelier.

2. *What are the requirements for entrance?*

A high-school diploma with better than medium grades in the academic or college-preparatory course, with a minimum age of eighteen years. Married students are now accepted in most schools.

3. *What are resources for financial aid for those unable to meet the costs of a three-year course?*

The federal government has appropriated \$3,500,000 for nursing education, part of which is available for scholarships to cover tuition and entrance expenses, uniforms, books and so forth. This fund is available to accredited schools of nursing in hospitals with daily averages of 90 to 100 patients, or to smaller schools affiliating with others to make a well-rounded course. Tuition costs range from nothing to several hundred dollars, but the average is \$75.00.

The Federation of Women's Clubs in all the states are undertaking aid to student nurses as one of their year's activities and will have scholarship funds for personal expenses for students.

Both these funds are assigned through the directors of the schools of nursing, to whom the students should apply.

Some schools will concentrate the instruction in the first two and a half years of training, paying the students for their services during the last six months.

4. *What is the future for these student nurses who now crowd the schools of nursing?*

New positions will inevitably be available in the Army and Navy Nurse Corps after the war, if larger military forces are maintained, as seems likely. Greatly increased numbers will be needed in veterans' services.

The field of public health, both in this country and in reconstruction in other lands, is due for expansion. Hospitals will again replace students with graduates after the war. Marriage will take its usual toll. The opportunities for the well-qualified nurse seem to be broadening. Some unemployment of the poorly equipped nurse will probably be unavoidable.

5. *What resources are available for the hospital that has no room for enlarged classes of student nurses?*

The federal fund of \$3,500,000 is available for extra subsistence, including housing, food and laun-

dry, for additional instructors and instructional facilities and for expansion of clinical experience through affiliation with other institutions. Hospitals with daily averages of 90 to 100 patients may qualify. Smaller ones may qualify through affiliation with other institutions and centralization of instructional facilities to form a well rounded modern unit for nursing education. Application should be made to the United States Public Health Service. Full details have been sent to every hospital.

These are the facts. We need the co-operation of physicians in helping nursing to meet the demands of the military services for graduates, and the requirements of the hospitals for new students.

Yours very truly,

HELENE G. LEE, *Executive Secretary*
Massachusetts Nursing Council for War Service

20 Boylston Street
Boston

WAR ACTIVITIES

CIVILIAN DEFENSE

PLANS FOR MORTUARY SERVICE

The Medical Division of the United States Office of Civilian Defense has issued *Medical Division Bulletin No. 5 Emergency Mortuary Services*, presenting plans for the organization of this essential part of the casualty services.

The bulletin suggests that the local chief of Emergency Medical Service, in co-operation with the medical examiner or coroner, the chief of police, the health officer and representatives of the private funeral directors and cemeteries, plan for the following necessary services: location of morgue facilities, administration of these facilities, training of supplementary mortuary personnel, responsibility for collection and preparation of the dead for burial, rules for emergency issuance of death certificates and burial permits, types of inquests, if any, to be required, safeguarding of personal property of the dead, manufacture of board coffins, pooling of equipment and personnel of private mortuaries in emergencies, identification procedures, burial places for unclaimed and unidentified bodies, preparation of mortality lists, and arrangements with adjacent communities for mutual aid.

Morgue facilities should include a main morgue, usually the community's public morgue, and supplementary morgues as necessary to provide space for bodies in a ratio of 2 per 1000 population in target areas. Skating rinks, gymnasiums, auditoriums and similar buildings are suggested.

The staff of the Emergency Mortuary Service as set out in the bulletin includes a physician to confirm deaths. Other members of the staff are the director, recorder, property officer, identification officer, coroner's or medical examiner's representative, morgue attendants, clerical assistants and receptionists.

It is recommended that the identification tags used in the field casualty service for wounded be attached also to the dead in the field. Whenever possible a physician should examine bodies before they are removed to a morgue, so that if there is doubt of death in any case, the body may be taken to a casualty station or hospital for observation.

The bulletin outlines procedures for the reception of bodies at the morgue, the handling of personal property,

the storage of bodies, identification and the release and disposal of bodies. Special measures for the handling of gas-contaminated bodies are described.

Federal funds are available under certain conditions to pay funeral and cemetery expenses. Mass disposal of bodies, either by burial in a common grave or by cremation, should be used only in the event of extremely large numbers of casualties which overwhelm regular and emergency mortuary facilities, and create a public health menace.

The bulletin deals briefly with the reporting of casualties and recommends that information be released through the Casualty Information Service. Plans are also presented for the safeguarding of valuables and for the collection and storage of the morgue records.

MISCELLANY

DR. WILINSKY'S SIXTIETH BIRTHDAY

On Sunday, December 20, approximately three hundred and fifty persons assembled at the Nurses' Home of the Beth Israel Hospital to honor the sixtieth birthday of Dr. Charles F. Wilinsky. The speakers included Judge and Mrs. Abraham E. Pinanski, Judge A. K. Cohen, Dr. James Hamilton, president of the American Hospital Association, and Dr. Samuel A. Robins. Dr. Wilinsky was presented with a handsomely bound volume containing several hundred congratulatory letters from his friends in various parts of the country, several checks of appreciation for the use of the Beth Israel Hospital and a portrait painted by Jacob Binder.

RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR OCTOBER, 1942

DISEASES	OCTOBER 1942	OCTOBER 1941	FIVE YEAR AVERAGE
Anterior poliomyelitis	7	46	19
Chicken pox	291	571	415
Diphtheria	13	8	15
Dog bite	842	857	806
Dysentery, bacillary	315	43	50
German measles	53	35	27
Gonorrhea	384	351	412
Measles	541	373	321
Meningitis, men. meningococcal	12	8	6
Meningitis, other forms	3	3	4
Mumps	401	335	197
Paratyphoid infection	13	6	3
Pneumonia, lobar	242	192	222
Scarlet fever	622	466	312
Syphilis	610	450	426
Tuberculosis, pulmonary	265	289	245
Tuberculosis, other forms	13	29	31
Typhoid fever	7	11	7
Undulant fever	6	6	4
Whooping cough	737	555	468

*Based on figures for preceding five years.

†Infeeb. bacillus meningitis only other forms reportable previous to 1915.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Braintree, Easton, 1, Fitchburg, 1, Fort Devens, 1, Salem, 1, Waltham, 1, Weymouth, 1, total, 7.

Diphtheria was reported from Billerica, 1, Blackstone, 1, Boston, 2, Fall River, 4, Lowell, 2, Springfield, Taunton, 1, West Brookfield, 1, total, 13.

Dysentery, bacillary, was reported from Lynn, 3, Quincy, 1, Salem, 1, Wrentham (State School), 309, total, 31. Encephalitis, infectious, was reported from Everett, Somerville, 1, total, 2.

Meningitis, meningococcal, was reported from Boston, 2, Cambridge, 1, Camp Edwards, 2, Dracut, 1, Everett,

Fall River, 1; Fitchburg, 1; Lowell, 1; Revere, 1; Woburn, 1; total, 12.

Meningitis, other forms, was reported from: Athol, 1; Boston, 1; Holyoke, 1; total, 3.

Paratyphoid infection was reported from: Boston, 2; Malden, 1; Norwood, 1; Quincy, 2; Somerville, 2; Southbridge, 1; West Boylston, 4; total, 13.

Septic sore throat was reported from: Boston, 6; Brockton, 1; Cambridge, 2; Winchester, 2; total, 11.

Trichinosis was reported from: New Bedford, 1; total, 1.

Typhoid fever was reported from: Becket, 5; Boston, 1; Milton, 1; total, 7.

Undulant fever was reported from: Danvers, 1; Gloucester, 1; Lexington, 1; Medford, 1; North Adams, 1; Whately, 1; total, 6.

Communicable diseases in general showed the usual seasonal increase.

Record-high figures were attained by mumps for the fourteenth time during the past sixteen months.

Whooping cough, German measles, paratyphoid infection, syphilis and bacillary dysentery were all reported at record-high figures. An outbreak in an institution is responsible for the high figures for bacillary dysentery.

Diseases reported at figures above their respective five-year averages were measles, meningococcal meningitis, lobar pneumonia, scarlet fever, dog bite, pulmonary tuberculosis and undulant fever.

The figure for typhoid fever was equal to the five-year average of the disease.

Reported at figures below their respective five-year averages were anterior poliomyelitis, chicken pox, diphtheria and gonorrhea.

Tuberculosis, other forms, was reported at a record low incidence.

Animal rabies was again reported from the focus previously mentioned in Norfolk County.

ARMY-NAVY "E" AWARD TO WINTHROP CHEMICAL COMPANY

On December 17, the Winthrop Chemical Company was presented the Army-Navy "E" award for its production of drugs essential to the war effort. The ceremonies were held in the morning at the plant in Rensselaer, New York, and in the evening at the Hotel New Yorker, New York City, for the employees in that city. Dr. Morris Fishbein was principal speaker at both occasions, and Brigadier General Charles C. Hillman and Rear Admiral Charles S. Stephenson made the award. Of the more than a hundred drugs being furnished by the Winthrop Chemical Company to the armed forces of the United Nations, the most important are Atabrine, Plasmochin, Naphuride, Avertin and the various sulfonamides.

NOTE

General Frederick F. Russell, professor of preventive medicine and epidemiology, emeritus, at Harvard Medical School, was recently awarded one of three William Crawford Gorgas medals by the Association of Military Surgeons of the United States. These medals and the attached honorariums have been made possible by a grant from John Wyeth and Brother, Incorporated, of Philadelphia, and the award to General Russell was based on his pioneer work in immunization against typhoid fever. The other recipients were Rear Admiral Edward R. Stitt and Brigadier General Jefferson R. Kean.

BOOK REVIEWS

Gynecology and Female Endocrinology. By Emil Novak, M.D., D.Sc. (hon., Dublin). 4°, cloth, 605 pp., with 11 illustrations. Boston: Little, Brown and Company, 1942. \$10.00.

The difference between this and earlier work on gynecology is clearly seen in the section on menstruation. It was only a few years ago that such a chapter was devoted to the anatomic description of what happened locally to the uterine wall. The present work tells a sequential story, which embodies endocrinology, physiology and anatomy, and the reader appreciates that he is beginning to get a view of what makes the wheels turn.

It is through the newer knowledge of endocrinology that a more rational approach can be made to both functional and organic disorders of the female generative tract. Dysmenorrhea, menorrhagia, sterility and habitual abortion are a few of the conditions in which the experimentalist has been helpful. In addition to presenting these innovations, the author also questions some of the older methods as experimental. For example, he states that the value of pregnant-mare serum in producing ovulation in women is still open to question. Busy clinicians require a sane evaluation such as this to overcome the obvious high-pressure methods of the commercial houses to promote their products.

Because of the many new things in this book, one is likely to overlook the very excellent discussion on pathology, which is presented with the help of numerous illustrations, including some excellent colored plates.

Dr. Novak has written this book primarily for general practitioners and medical students, and operative technique has been deleted. The material has been judiciously selected, and the style of writing moves smoothly like a well-told story. The result is the finest work on gynecology in many years.

Solving School Health Problems: The Astoria demonstration study. Sponsored by the Department of Health and the Board of Education of New York City. By Dorothy Nyswander, Ph.D. 8°, cloth, 377 pp. New York: Commonwealth Fund, 1942. \$2.00.

This volume presents the details of a four-year study of school health services in New York City carried on during the period from 1936 to 1940. It outlines and discusses problems of administration, record forms, nurse's duties and opportunities, teacher's participation, dental care and tests for visual and for auditory acuity, including the presentation of many forms and blanks that have been found useful.

The following quotation gives an idea of the progress and outlook of the study as a whole: "Statistics of defects found and defects corrected furnish no index of school health problems which any individual child may develop later; they offer no index that the larger objectives of school health service are being reached; they give no evidence of the quality of work performed; they are not adapted to a single good supervisory technique which seeks to find out how to give better continuing supervision to individual children." This better-continuing supervision is dealt with in a positive way wherever possible.

The book is one of quality, and worthy of the care with which it has been printed and bound. It should be of interest to all school health administrators — physicians
